Circulatory collapse in tourniquet shock is due to a reduction in blood volume caused by (a) loss of fluid into injured limbs and (b) sequestration of blood from the active circulation by pooling in the capillary bed and collecting venules. The latter is due to the development of a hyporeactive factor which progressively interferes with the peripheral vascular compensatory mechanisms.

EFFECTS OF THE PARENTERAL ADMINISTRATION OF FLUIDS ON THE METABOLISM OF ELECTROLYTES DURING POSTOPERATIVE CONVALESCENCE

EDWIN M LIMBERT M D MARSCHELLE H POWER, Ph.D., JOHN DeJ PEMBERTON
M D., F.A.C.S., and E. G WAKEFIELD M D Rochester Minnesota

THE therapeutic value of the intravenous administration of fluids during the course of any illness in which it has been difficult to maintain adequate fluid intake by mouth or in which the loss of fluid has been excessive is well established. However the administration of large amounts of fluid directly into the blood stream may occasionally produce unforeseen and inexplicable complications. Varying degrees of edema after repeated administration of fluids intravenously may be rationally explained as a complication of the sodium chloride and water which have been administered. After this obvious reason for edema has been evaluated such causes as malnutrition, loss of protein by drainage or hemorrhage, sepsis and impaired renal function may be given the etiologic credit they deserve.

Our interest concerning the intravenous administration of fluids pertains to certain practical aspects of therapy. Most of the literature on this subject suggests that a middle-of-the-road course be pursued when fluids are to be administered parenterally. For example one should administer a liter of physiologic saline solution and a liter of a 5 or 10 per cent solution of dextrose in distilled water or equal parts of these solutions. A patient who receives 3,000 cubic centimeters of a solution containing 0.45 per cent of sodium chloride solution or 1,500 cubic centimeters of physiologic saline solution during 24 hours receives 12.75 grams of sodium chloride which is 4 or 5 grams more sodium chloride than is ingested in the normal diet. A physiologic solution of sodium chloride however is the favorite solution for intravenous administration in spite of warnings concerning its injudicious employment. Coller

Dick and Maddock have shown that retention of water is a frequent occurrence after the administration of solutions of sodium chloride to patients who are very ill after surgical operation. However the parenteral use of isotonic solutions of sodium chloride possibly has become a habit because this solution may be a means of saving the lives of many patients who have an intestinal obstruction both before and after surgical treatment. Also there is abroad the general idea that intravenous administration of fluid produces a greater diuresis than does oral administration of the same amount of fluid. Of course the varying conceptions of the diuretic effects of oral versus parenteral administration of fluid is unimportant. No one would administer fluid intravenously in a case in which an adequate amount of fluid could be administered by mouth. Fantus has appropriately suggested that the intravenous administration of fluid produces less diuresis than does oral ingestion. Matas has emphasized what he considered the dangers of the administration of isotonic solutions of sodium chloride. It may be said therefore that the parenteral administration of isotonic solutions of sodium chloride is universal and that the procedure is not often complicated by any very grave untoward effects. The object of the present study was to determine if possible what changes occur in the excretion of the fixed bases and chlorides during the prolonged intravenous administration of isotonic solutions of sodium chloride (1 per cent) and solutions of dextrose (5 or 10 per cent) or mixtures of these solutions.

MATERIAL AND METHOD

The cases selected for study were those in which under ordinary circumstances large amounts of fluid would be administered intra-

From the Division of Biochemistry, The Mayo Foundation, and the Division of Surgery and Medicine, The Mayo Clinic.

Fig. 1. Daily intake and output of fluid.

venously. They were all cases of carcinoma of the colon in all of the cases the involved segment of the colon had been resected. The usual postoperative treatment was not altered in any manner. Blood was collected within an hour after the operation and again at the conclusion of the study. The urine was collected and the total amount obtained in each 24 hours of the period of observation was examined. In Case 4 an indwelling catheter permitted the accurate collection of the specimens of urine. In the other cases the patients were often unable to micturate at the end of each day. However the total collections of urine during the periods of study were reasonably accurate. Vomitus and duodenal drainage were also collected. The one patient who passed feces during the period of study was given a tablespoonful of powdered charcoal at the end of the final period of 24 hours and all feces passed prior to the appearance of the charcoal were collected in one container. The results of the analysis of this specimen were included in the output for the last day (Case 3 6th day). Samples of the solutions of sodium chloride that were injected were analyzed and the composition was found to be almost uniform. The average composition of the analyzed samples served as a basis for computing the intake of sodium and chloride. The Ringer solutions administered in Case 5 were individually an-

alyzed. Aliquot samples of the various fluids which were given orally were mixed and analyzed. During the entire period of study the patient in Case 1 received only a 5 per cent solution of dextrose. If the dextrose that was administered parenterally was utilized, 1770 calories were thus administered. In Case 1. Similarly the patient in Case 2 received 1,120 calories in 5 days; the patient in Case 3 received 1,796 calories in 6 days; the patient in Case 4 received 3,207 calories in 7 days; and the patients in Cases 5 and 6 received 3,485 and 4,777 calories respectively in 8 days.

Samples of blood for the analyses were collected under oil in tubes containing heparin. The following analytical methods were employed for plasma sodium the method of Butler and Tuthill for plasma potassium, Hartzler's modification of the method of Shohl and Bennett for chlorides in plasma, the method of Keys for calcium in plasma, the method of Tisdall and Kramer for magnesium in plasma, the method of Denis. The amount of base contained in foods, feces, and urine was determined on ashed samples by means of the same procedures as used for the determination of the amount of sodium, potassium and magnesium in the blood plasma. The calcium was precipitated as the oxalate by a modification of the method of Washburn and Shear. The amount of chloride in the urine

Fig. 2. Daily intake and output of sodium and chloride.

was determined by the open Carus method by means of reagents suggested by Peters and Van Slyke

RESULTS

The greater part of the fluid intake was given parenterally but toward the end of the period that each patient was being studied small amounts of water were taken by mouth as sips. Occasionally the sips consisted of fruit juices. When the fluid was fruit juice or other liquid food an aliquot was taken for analysis and the volume was included in the total intake. Figure 1 is a graphic representation of the daily intake and output of fluid. At the end of the period of study in each case is given an average of the daily intake and output of fluid. When a transfusion was given the total volume of blood was included in the fluid intake and the total amount of sodium, potassium, magnesium, calcium and chloride of the blood was added to the total intake of these substances. In one case (Case 5) the patient received Ringer's solution in the last 2 days of observation and the amount of base and chloride of this solution was likewise included in the results of the analysis of the intake. As is indicated in the graph the fluid output exceeded the intake only once and that was in Case 3 on the 4th day of the study. The

volume of the total fluid output is the sum total of the fluid lost in the urine by duodenal suction and on one or two occasions in vomitus. The total output of sodium, potassium, magnesium, calcium and chloride includes the amount of these substances lost in the vomitus, duodenal fluid and urine. The amount of fluid and electrolytes lost through sweating and respiration could not be accounted for in this study. The experimental work was done in cool weather. The losses of electrolytes through the sweat probably were not of very great importance.

The daily intake and output of sodium and chloride is shown in Figure 2. In Figure 3 the averages of the daily excretion of sodium and chloride are shown. Only in Case 4 did the average excretion of these substances exceed the average intake. Each individual displayed marked differences in the exchange of sodium. In Cases 1 and 2 (Fig. 2) the patients excreted a very small percentage of the total intake of sodium. At the end of the period of observation we were unable to account for 1,244 milliequivalents of sodium in Case 1 and 952 milliequivalents of sodium in Case 2. In Case 3 the patient apparently retained 636 milliequivalents of sodium during the first 3 days. However, during the 4th day 3,440 cubic

Fig. 3 Average daily excretion of sodium and chloride.

centimeters of a 5 per cent solution of dextrose were given intravenously 165 cubic centimeters of water were administered orally and 4,050 cubic centimeters of urine were excreted. This large volume of urine contained a half of the 636 milliequivalents of sodium which had been retained or were not accounted for. At the end of the 6-day period of observation however there were still 246 milliequivalents of sodium which were unaccounted for and thus probably retained. In Case 4 the excretion of sodium exceeded the ingestion of sodium by 38 milliequivalents during the 7 day period of study. The intake of sodium in this case was 39 milliequivalents which is 260 milliequivalents less than the average daily intake of 299 milliequivalents in all the cases studied. In Case 5 the patient excreted only 1,517 of the total 2,338 milliequivalents received which leaves 821 milliequivalents unaccounted for or retained. In Case 6 the patient maintained an output of fluid which was consistently higher than that excreted by any of the other patients, yet 483 milliequivalents of sodium were unaccounted for or retained at the end of the 8 day period of study.

Generally the intake of chloride was the same as the intake of sodium since the chloride salt of the sodium was administered parenterally. The excretion of chloride (Fig. 2) was not the same as the excretion of sodium except approximately in Case 3 (Fig. 2). In all of the other cases more chloride than sodium was excreted. The greatest loss of chloride was ob-

served in Cases 5 and 6 and this loss of output probably can be accounted for by the fact that in these 2 cases large volumes of fluids were removed by means of duodenal suction.

The intake of magnesium and calcium was mostly that included in the liquids administered by mouth and transfusion. The daily intake of magnesium for all patients varied from none at all to 2.9 milliequivalents. The daily excretion varied from 1.4 to 15.3 milliequivalents. The intake of calcium varied from none at all to 5.5 milliequivalents and the excretion varied from 0.6 to 13.9 milliequivalents. The excretion of calcium approximately paralleled the excretion of magnesium.

The intake of potassium was mainly that received by blood transfusion.

The excretion of potassium seemed to be definitely increased during the first 4 post-operative days. This increased excretion of potassium is probably the same phenomenon observed by Gamble, Ross, and Tisdall and Benedict during fasting. They observed that in the early days of a fast the excretion of potassium was from two to three times greater than during equal periods later in the fast. Gamble, Ross and Tisdall expressed the opinion that increased excretion of potassium was related to a reduction in the stored glycogen and consequent loss of the intracellular water in which it had been dissolved. Silvette, Britton and Kline agreed with Gamble, Ross and Tisdall, concerning this increased excretion of potassium. Byrom found that the increased initial loss of potassium occurred if ample supply of carbohydrate was administered but could be prevented if both potassium and carbohydrate were given. A most important, but not a new conception of the loss of potassium was advanced by Thaler who observed that the excretion of potassium was increased if the intake of sodium chloride was increased. Sodium and potassium are closely related chemical bases and deranged concentrations in physiologic fluids or in fluids administered are liable to be accompanied by deranged excretions.

The intake of nitrogen was not determined. The nitrogen like potassium, was mainly included in the blood transfusion. The daily excretion of nitrogen varied from 2,370 to

15763 milligrams The excretion of nitrogen tended to be low during the first postoperative day and higher than the average during the 3 succeeding days.

Generally the concentrations of sodium potassium calcium magnesium, chloride hemoglobin and the hematocrit reading showed no great change.

In spite of the large intake of sodium and chloride (the intake of sodium averaged 299 milliequivalents per day in all cases) the concentration of the sodium and chloride in the plasma remained approximately constant or was reduced in all cases. It is of interest here to recall that considerable amounts of sodium were retained or unaccounted for in all cases except Case 4. The total concentration of base in the plasma paralleled that of the sodium and was generally slightly reduced. Reduction in the concentration of the hemoglobin and a decrease in the normal hematocrit reading were the rule and probably indicated that the blood had been diluted.

COMMENT

The patients observed in this study differ in several respects from one who is being starved. They all had had an anesthetic and an abdominal operation and fluids containing sodium chloride and solutions of dextrose were administered. However little nourishment was taken by mouth. In the first few days of starvation according to Gamble and his co-workers destruction of protoplasm with its attendant loss in body weight is accompanied by losses of intracellular and extracellular bases chiefly potassium and sodium and body water from the intracellular and extracellular compartments in such amounts that the base content of the plasma and extracellular fluids bathing the cells remains essentially unchanged. Our Case 4 was the only one in which we observed a negative sodium balance comparable to that seen in starvation. In the other 5 cases the patients apparently retained much of the administered sodium and the concentration of sodium in the urine was relatively low rather than high. At the same time the average volume of urine excreted during the 24 hour period by our patients was less than the optimal normal excretion of 1500 cubic centi-

meters. It seems evident therefore that the retained sodium in these cases was accompanied by an appropriately equivalent retention of water—a finding which is in harmony with the interpretation of numerous studies on the relationship between base and water metabolism. Much of the water injected was consequently not available for replacement of fluid lost by evaporation perspiration or in the urine which together should amount to about 3500 cubic centimeters in adults according to the standards proposed by Collier, Dick and Maddock.

That the foregoing conditions may not be optimal for the performance of normal physiologic functions by the kidneys is illustrated by the data obtained in Case 5. During the 8 day period of study 2338 milliequivalents of sodium were administered. Fifteen hundred and seventeen milliequivalents or not quite two-thirds of the sodium were excreted. The concentration of sodium in the urine increased until it reached 161 milliequivalents per liter on the 6th day. The concentration of sodium in the urine then diminished rapidly to 62 milliequivalents per liter on the 8th day. The specific gravity of the urine decreased from 1.023 to 1.008. We have observed that oliguria and practically an anuria can be produced by the administration of sodium chloride in cases in which renal function is decreased. The data in this study seem to indicate that the functional activity of the apparently normal kidney at times may be reduced greatly by the administration of sodium chloride. The impression that normal kidneys can be depended upon to retain what the body needs and excrete the excess is so nearly true that this belief may be dangerous. The elasticity of normal renal function is enormous. It should however be kept in mind that once any organ is overloaded fatigue may come on rapidly and prove disastrous.

The parenteral administration of physiologic saline solutions during intestinal obstruction in cases in which chloride has been lost produces such immediate benefits that one feels that physiologic solutions of sodium chloride are always safe to administer in large quantities. Nothing is farther from the truth. Certain fundamental facts must be kept in mind

Fig. Daily Intake and output of field.

venously. They were all cases of carcinoma of the colon in all of the cases the involved segment of the colon had been resected. The usual postoperative treatment was not altered in any manner. The impression that normal kidneys can be depended upon to retain what the body needs and excrete the excess is so nearly true that this belief may be dangerous. The elasticity of normal renal function is enormous. It should however be kept in mind that once any organ is overloaded fatigue may come on rapidly and prove disastrous.

The parenteral administration of physiologic saline solutions during intestinal obstruction in cases in which chloride has been lost produces such immediate benefits that one feels that physiologic solutions of sodium chloride are always safe to administer in large quantities. Nothing is farther from the truth. Certain fundamental facts must be kept in mind

and no formula can be given to guide those who wish to ignore these facts. The average diet contains approximately 2 grams of sodium (equivalent to about 5 grams of sodium chloride) although one may take as much as 10 or more grams of sodium chloride daily. It is interesting to compare an intake of 10 grams of sodium chloride with the amount received by a patient who is given 3 000 cubic centimeters of physiologic saline solution intravenously. The patient receives about five times the average daily intake of sodium chloride required for the healthy adult and two and one half times as much as the individual who through habit has taken 10 grams daily. It is by ignoring these simple facts that patients who have not lost chlorides by vomiting by duodenal drainage or by extensive burns of the surface of the body often leave the hospital after surgical operations with a small amount of dependent edema, probably nutritional in origin."

SUMMARY

During postoperative parenteral administration of solutions of sodium chloride to patients who were not taking food considerable retention of sodium occurred in 5 of 6 cases. The concentration of base in the plasma did not change appreciably. The volumes of urine

were less than optimum, and 1 patient became unable to excrete concentrated urine, possibly as the result of the administration of too much sodium chloride. Under these conditions water must be retained with base and we wish to emphasize that water administered in the form of physiologic saline solution is not available for the important requirements of evaporation and perspiration.

THE TREATMENT OF THROMBOPHLEBITIS

MELVIN D YAHN M.D. CARL REICH M.D., and CARL EGGERS M.D. F.A.C.S.
New York, New York

THE disabling and sometimes disastrous consequences of venous thrombosis are well known to every physician. The etiology and resultant pathology of this condition have been subjects of varied opinions since John Hunter first described thrombosis as a sequel of phlebitis. The treatment has not changed much however as it has been little except symptomatic. During the past few years anticoagulant therapy has gained prominence in the treatment of thrombophlebitis and its associated complications.

The first of these substances used was heparin after its purification by Murray and Best. This substance however has certain inherent difficulties in regard to its use; it is expensive, must be given intravenously, frequent determination of coagulation must be done, its results are not predictable and its margin of safety appears to be narrow.

With the discovery of dicumarol¹ by Link (3) and his associates in 1940, an anticoagulant not presenting most of these difficulties was made available for the treatment of thrombotic phenomena.

Some investigators have tried dicumarol in the treatment of thrombophlebitis and have reported favorable results. On the other hand there has been some adverse comment about the use of anticoagulants in the treatment of thrombophlebitis. The main criticism according to DeBakey has been that the series of investigations are not adequate nor are the results sufficiently impressive to justify definite statements.

In an effort further to evaluate the use of dicumarol we have subjected all patients with thrombophlebitis to a uniform type of therapy.

This series consists of 67 cases of thrombophlebitis and its complications. We have arbitrarily divided the cases into four groups:

This work was done under a research grant from the Wm. G. Kaeser Fund, Lenox Hill Hospital.
Technical assistance and procedure by Miss Ruth Lipkin, A.B.
Dicumarol furnished by Dr. G. R. Hazel of Abbott Laboratories.

on an anatomical basis. These consist of (1) superficial phlebitis, (2) deep phlebitis, (3) superficial and deep, (4) pulmonary embolization with or without a demonstrable phlebotic site.

The treatment and results for each group are discussed separately. Prothrombin times were done daily. The technique using the method of Shapiro with modifications is indicated below.

TECHNIQUE

1. Remove lung from freshly killed rabbit.
2. To remove blood, wash lung for about 15 minutes in cold running water. Blot out excess with filter paper.
3. Cut in small pieces, place in evaporating dish.
4. Place dishes in desiccator (Drying agent barium dioxide). Attach to suction apparatus to form a vacuum for about 10 to 15 minutes.
5. Place desiccator in incubator at 37 degrees for 24 hours. (Drying process).
6. Remove pieces of lung from desiccator, grind finely in mortar.
7. Keep in refrigerator (Good about 4 weeks.)

THROMBOPLASTIN

1. To 100 milligrams of rabbit's lungs (thromboplastin).
2. Add 5 cubic centimeters of normal physiological saline (0.8%).
3. Inactivate thromboplastin for 10 minutes in water bath at 57 degrees C. Stir constantly.
4. Remove from water bath and stir until thromboplastin reaches room temperature.
5. Add 5 cubic centimeters of calcium chloride (1:11 gr to 500 c.c.). Shake thoroughly.
6. Centrifuge for 4 minutes at 1800 revolutions. Use supernatant fluid.

OBTAINING BLOOD SPECIMEN

Using 20 gauge needles take 4-5 cubic centimeters of blood to 0.5 cubic centimeters of sodium oxalate (1:34 to 100 c.c.). Centrifuge, remove plasma.

PROTHROMBIN DETERMINATION

1. Place plasma in water bath kept at a constant 38 degrees temperature.
2. In small tubes add 0.2 cubic centimeter of thromboplastin.
3. To thromboplastin add 0.1 cubic centimeter of whole plasma. Start stop watch immediately. Use

a wire loop to pick up complete clot when it is formed
Record time of result.

SUPERFICIAL PHLEBITIS

In this group there are 11 cases 8 female and 3 male. The ages varied from 25 to 61 years 4 were postpartum 2 antepartum and 5 were cases of phlebitis of long standing unassociated with any known etiological factor. All of these patients were treated in the same fashion. Dicumarol was administered in sufficient dosage to keep the prothrombin time prolonged to double the normal value of that particular patient.

Wet boric acid dressings were applied continuously to the affected area and $\frac{1}{8}$ grain papaverine was given at irregular intervals for excessive pain. The average number of days in bed was 10 and the criteria taken for remission of the attack were diminution or disappearance of pain or tenderness over the affected areas, as well as normal temperature and pulse. Dicumarol was discontinued when these conditions were fulfilled and the patient was then allowed out of bed and active motion, usually with the application of an Ace bandage encouraged. The average total dose of drug was 1000 milligrams.

These patients have been followed for an average of from 6 to 10 months with no further recurrences reported to date. It is interesting to note that Case 7 had had repeated attacks of phlebitis during the past 10 years, each lasting from 3 to 4 months. This patient was out of bed and feeling well in 9 days and has had no further symptoms. Two interesting cases, especially from the standpoint of the obstetrician, Cases 1 and 10 in this group, were 2 antepartum patients who developed severe superficial phlebitis during the 7th and 3d months of pregnancy respectively. Patient 1 had marked tenderness and redness along the course of almost all the superficial veins of the thigh. No primary site of infection could be found. The patient was immediately started on the aforementioned regimen. On the 4th day when the patient was in the therapeutic range she was entirely free of pain for the first time. By the 10th day she was completely asymptomatic, and then was allowed out of bed. She was followed through-

out the rest of her pregnancy and did not develop recurrence of phlebitis. Two months later she delivered a normal male child. There was no excessive bleeding at the time of delivery and the baby showed no untoward effects due to dicumarol. The patient was followed during her postpartum course but showed no signs of phlebitis. The other patient also showed good response but had not reached term at the time of this report.

Although this series of cases is small, they are representative of the type of superficial phlebitis usually observed. The rapidity of response to therapy and the long remission encourages one to continue further therapy along these lines. It is further interesting to note that in none of these cases was there an attempt to control infection *per se* with either chemotherapy or other antiseptic agents.

DEEP PHLEBITIS

This group contains 27 patients. Nineteen of these were females 8 males. The ages varied from 18 to 67 years. Four of these patients were postpartum 16 were postoperative and the 7 remaining without any etiological factor. All of these patients were treated in the same way. Dicumarol was begun as soon as the diagnosis was made. The involved extremity was elevated, a cradle placed over the limb, and an ice bag applied to the point of maximum tenderness. The method of administering dicumarol was the same as described and prothrombin times were done daily. The largest dose administered was 2300 milligrams. The smallest was 500 milligrams. The criteria for remission were normal temperature and pulse, lack of tenderness over the affected veins as well as loss of pain and marked decrease in the amount of swelling. When these criteria were fulfilled the patient was allowed out of bed and an elastic stocking or an Ace bandage was applied. The prothrombin time was kept within the therapeutic range for at least 24 hours after patient got out of bed.

Under this regimen the average time in bed was 10.5 days with a range of 5 to 23 days. Pain usually subsided within 24 hours after the patient's prothrombin time was in the therapeutic range. Little if any sedation was needed during the rest of the course. Most

significant is the fact that there were no episodes of pulmonary embolization. The thrombotic process appeared to remain localized. No untoward effects from dicumarol occurred. In Case 13 the prothrombin time went as high as 70 seconds but there was no evidence of hemorrhagic phenomena.

SUPERFICIAL AND DEEP PHLEBITIS

There are 9 patients included in this group, 7 of which were female and 2 male. The age distribution was from 30 to 72 years. Five cases were postoperative hysterectomies, 1 was an antepartum patient in her 8th month and 3 were phlebitis without any known etiological factor. The regimen followed in these cases was the administration of dicumarol as here outlined above, elevation of the leg, wet boric acid dressings to the affected area, and papavarine in doses of $\frac{1}{2}$ grain every 4 hours for pain. The largest total dose administered in these cases was 1400 milligrams and the smallest 600 milligrams.

These patients remained in bed for an average of 14.7 days with a range of 7 to 25 days. There were no complications referable to embolic phenomena nor were there any toxic effects due to dicumarol. Patient 1 was a primipara who developed redness and a slight swelling over the medial aspect of the lower extremity just below the knee. There was marked tenderness over the short saphenous vein. The regimen outlined was initiated and the symptoms subsided within 7 days. This patient was delivered of a normal male child 2 months later. There were no concomitant hemorrhagic phenomena.

The second interesting case, Case 2, was a patient 72 years old. He had had a chronic phlebitis for the past 10 years. There was definite evidence of superficial and deep phlebitis. The regimen outlined was instituted and the patient was kept under therapy for 15 days. There was apparent subsidence of phlebotic symptoms and therapy was discontinued. The follow up course showed persistent edema. Three weeks later this patient suddenly went into coma and died despite supportive therapy. An autopsy showed fresh thrombosis throughout the iliac veins involving the vena cava.

Patient 7 was admitted in 1936 for a salpingo-oophorectomy. Eight days following the operation she developed deep phlebitis of the lower extremity and 10 days later a pulmonary embolus. She remained in the hospital for 3 months on symptomatic therapy. She was readmitted in 1939 with swelling of the leg as well as pain in chest, cough and blood tinged sputum. The diagnosis at this time was recurrent phlebitis with pulmonary embolism. From 1939 to 1943 this patient was seen on numerous occasions in the clinic, complaining of pain and swelling in one lower extremity. She had had various forms of therapy including application of leeches, cold compresses, elevation of the part, with little result. In 1943 she was admitted to the hospital for repair of ventral hernia. This time she had a slight swelling of the left lower extremity, with tenderness and redness along the medial aspect. The usual regimen was begun. Patient was kept on dicumarol for 16 days. This time the prothrombin time was allowed to return to normal and the ventral hernia repaired. On the 3d postoperative day dicumarol was again begun and she was kept in therapeutic range for the next 10 days. She was discharged with no symptoms of active phlebitis.

PULMONARY EMBOLIZATION

This group includes 10 patients, 7 of which were female and 3 male. Age distribution varied from 28 to 65 years. There was no previous history and there were no symptoms of phlebitis in any of these cases, the first symptoms being those referable to embolus of the lung. Eight of the patients had one pulmonary embolus while 3 had two episodes. These patients fit into the group described by Homan as silent thrombophlebitis in which the first symptom is referable to the embolus and not to the original phlebotic site. In 8 of the patients the conditions were postoperative, each patient having had some type of pelvic operation. The most obscure case was that of a 65 year old woman who had a typical episode of pulmonary infarction of unknown etiology.

All patients were treated in the same fashion. Dicumarol was begun as soon as the pa-

tient was seen and continued in sufficient doses to keep the prothrombin time elevated to twice its normal value. The only other therapy was an adequate amount of sedation to control pain.

While under therapy none of these patients had any further episodes of pulmonary emboli. This held true even for those who had more than one previous episode. These patients remained in bed an average of 14 days the longest time being 20 the shortest 13. One patient was found to be resistant to the ordinary dose of dicumarol. The prothrombin time in this case was never raised above 25 seconds. When a second group of pulmonary emboli occurred she was treated with heparin.

The results in this group of patients were fairly uniform while under treatment. There were no toxic effects due to dicumarol, and the drug was administered and controlled without difficulty.

SUMMARY

The above presentation not lending itself to statistical analysis indicates some interesting points in the therapy of phlebitis.

The diminution in the length of time of treatment, the lack of complications referable to phlebitis as well as to dicumarol make this form of therapy worthwhile. None of these cases while under treatment or in the post-treatment period developed emboli. In those cases, having had previous embolic phenomena, there was no further evidence of it after therapy was begun. Further in none of the 67 patients did other foci of thrombophlebitis occur either in the treatment or posttreatment periods.

Pain which is an outstanding feature of thrombosis, is markedly decreased in direct relationship to the initial elevation of the prothrombin time i.e. when the patient is in the therapeutic range the amount of sedation needed is markedly diminished. This very interesting feature was first pointed out by Zucker.

In contrast to other types of anticoagulant therapy dicumarol appears to have a wider margin of safety. Prothrombin time in these cases varied between 15 and 70 seconds. Despite this marked prolongation of the pro-

thrombin time there was no evidence of hemorrhagic diatheses.

We must not, however, develop a false sense of security in this wide margin of safety: each individual varies in his response to a given dose of dicumarol. Consequently prothrombin times must be done daily or at least preceding the administration of any given dose. Reference to the tables of any group of patients presented will indicate that despite the uniformity of the initial doses, subsequent doses varied markedly.

The initial doses consisted of 300 milligrams the first day and 200 milligrams the second day. Following these doses from 20 to 200 milligrams in 24 hours were given. To guide to the proper dose was the prothrombin time. If after 500 milligrams the prothrombin time had risen to double its initial value a further dose was given. If it was rising rapidly but had not reached the therapeutic range i.e. double its initial value no dose was given. If there was no rise or it was rising slowly from 50 to 200 milligrams was given depending upon the initial elevation. This scheme was followed throughout the course.

Under this regimen there usually was latency of 24 to 72 hours before the prothrombin time was affected. One must be wary of overdosage during the latter part of the latent phase. The third dose in our cases was almost always 100 milligrams.

Of the patients treated there were 37 treated for postoperative sequelae: 22 were antepartum and postpartum cases, and 15 were phlebitis cases without known etiological association. Dicumarol was begun during various intervals of the postoperative period, but in no case was it necessary to begin treatment before the 3d postoperative day. As far as could be determined there was no interference with wound healing and no hematomas developed. In the obstetrical cases, 19 of which were postpartum there was no increased vaginal bleeding nor was the postpartum period affected in any way. In these cases dicumarol was begun as early as 24 hours following delivery. Three antepartum patients had normal deliveries, one of these having received dicumarol in the last month of the third trimester.

In these series only one resistant case was encountered and her prothrombin time did not go above 20 seconds despite a total dosage of 2100 milligrams.

We have had little experience with other methods of treating thrombophlebitis, such as paravertebral procaine sympathetic block or venous section with ligation. This latter procedure was used in one case of deep phlebitis of the femoral vein combined with anticoagulant therapy. However the lack of complications due to either the thrombophlebitis or dicumarol would seem now to make anticoagulant therapy alone the procedure of choice.

THE SURGICAL ANATOMY OF THE FACIAL NERVE

With Special Reference to the Parotid Gland

LAWRENCE J. McCORMACK, M.B. EARL W. CAULDWELL, M.D. and
BARRY J. ANSON, Ph.D. (Med. Sc.) Chicago, Illinois

ALTHOUGH the incidence of parotid tumor may be as low as 0.06 per cent (Sistrunk, 1921) treatment of the lesion is fraught with such difficulty that any aid offered by anatomy to the surgeon, would be of value. While injury to the facial nerve is not vitally damaging the resultant cosmetic deformity brings great psychic distress to the patient. In an attempt to avoid the latter effect roentgen therapy has often been resorted to in the management of these tumors. Bailey (1941) arguing for total parotidectomy calls attention to the radioresistance of most of the tumors; he also mentions the great tendency to recurrence because of the technical difficulties involved in the operative procedure. McFarland (1933) in studying over 400 cases, reported a 30 per cent recurrence of parotid tumors locally removed especially those of smaller size.

Many authors have discussed the surgery and pathology of the parotid area, but relatively little has been written about the exact relation of the gland to the facial nerve. The most extensive anatomic study of the nerve (Tortella, 1935) is based upon only seven specimens. The purpose of the present study therefore is to furnish such information on the nerve and parotid gland accumulated from a large series of specimens.

MATERIALS AND METHODS

The series herein reported upon consists of 100 facial halves selected from specimens in the anatomical laboratories of Northwestern University Medical School.¹ The specimens were adult whites and negroes (79 white, 21 negro) mostly male (82 males, 18 females). Only specimens with complete dissection of the facial nerve were included. No attempt was made to study bilateral configurations.

A fixed method of exposure was followed, devised to preserve the relationship of the gland to the nerves. The skin and superficial fascia over

the parotid area were carefully removed, from posterior to anterior. The free anterior border of the parotid gland was then mobilized, and a careful search was made for the emerging branches of the facial nerve, particularly the temporal and zygomatic portions. The mandibular and cervical divisions were next uncovered along the anterior-inferior border of the gland. These divisions being used as guides, the dissection was then carried into the gland itself. In virtually all instances, a natural cleavage plane was found to exist between the lobes of the gland which allowed the dissection to locate the main trunk of the nerve at its point of division. Careful individual drawings of the area were then prepared to show the configuration of the main portions of the nerve and the anastomoses between its adjacent divisions and branches.

In the greater number of the specimens (66) the distance between the point of bifurcation of the nerve and the external angle of the mandible was recorded (Table I). In 75 specimens the height and width of the parotid gland were measured, and the shape recorded. The presence or absence of accessory glands and the general configuration and course of the main parotid duct were also noted.

All of the illustrations were prepared from specimens selected from the series.

OBSERVATIONS AND DISCUSSION

Developmentally the relationship of the parotid gland to the facial nerve is a secondary one, since the gland migrates backward from its original site of pharyngeal outpouching. Controversy however has developed as to the mode of formation of the lobes of the gland. Grégoire (1911)

¹Contribution from Anatomical Laboratory of Northwestern University Medical School.

Approximately 30 additional specimens were examined although imperfect in respect to some details of nervous branches; their general structure would support all statements made hereinafter.

Figs. 1 to 3. Facial nerve and parotid gland superficial and deep dissections. Adult male, negro. Showing the divisions and ramification of the nerve and their relation to the gland, and to the mandible and zygomatic arch. In Figure 3, lower right, the margin of the deep lobe (broken line) and isthmus (cross-hatching) are shown diagrammatically.

from a study of 60 adult and 8 fetal glands, concluded that the deep lobe was formed by a migration of a portion of the superior pole of the gland the latter retaining connection with the superficial lobe which remained situated above the facial nerve. McWhorter (1917) from an examination of 66 adult parotids and 16 in fetal and newborn specimens, was, on the contrary, of the opinion that the gland was H-shaped with the connecting arm (or isthmus) between the two diverging portions of the facial nerve. Rouvière and Cordier (1934) after reconstructing two glands, came to the conclusion that both Grégoire and McWhorter were correct. In the 31 millimeter fetus the gland

was found to be entirely superficial, while in the 51 millimeter fetus there were projections which passed over the facial nerve superiorly as well as some which passed between the two portions of the nerve to form a deep lobe.

The present authors found that the general relationships which were described by McWhorter were recognized in their specimens. The facial nerve, lying between two lobes of the parotid partially separates the gland into a large superficial and a small deep portion, the two parts being connected by a slender isthmus which passes between the two diverging portions of the nerve (Fig. 3).

Figure 7 demonstrating the relation of the nonanastomotic type of nerve to the zygoma, mandible and masseter muscle. In Figures 6 and 7 the parotid duct has been cut.

A Facial Nerve

After the facial nerve emerges from the skull through the stylomastoid foramen, it passes inferiorly with slight anterolateral inclination to plunge into the substance of the gland. With the exception of one or two small muscular rami all of its branches are given off after it has entered the parotid. Regularly the single main trunk splits

into two principal divisions, the temporofacial and cervicofacial portions. The point of bifurcation occurs 5 to 7 millimeters dorsal to the ramus of the mandible, where the nerve is entirely surrounded by glandular tissue. In 66 specimens it was found to be a distance of from 1.4 to 4.7 centimeters above the external angle of the mandible, measured along the palpable posterior border of

the ramus (Table I). Most of the specimens fall in a group between 2.9 and 4.4 centimeters (an interval distance of 1.5 cm.) the average measurement is 3.4 centimeters. Converted into a rough measurement of surgical value, the point of bifurcation of the facial nerve lies posterior and slightly medial to the ramus of the mandible and superiorly two-thirds of the distance between the external angle of the mandible and the palpable condyloid process (temporomandibular articulation). Much of the absolute variation in distance is explained on the basis of comparative head size: the greater the cranial and mandibular development, the greater will be the interval.

Of the two principal divisions of the facial formed at the point of bifurcation, the temporo-facial portion, supplying the upper part of the face is by far the larger (Figs. 1 to 7). It is often two to three times the size of the cervicofacial component. The upper division courses anterosuperiorly just below the upper border of the parotid gland. In the first part of its course it lies between the two lobes of the gland (see hereinafter). The lower division arches downward between the two lobes in close association with the posterior border of the ramus of the mandible.

The pattern of branching from the two main divisions which is described in anatomical text books, was found to occur infrequently in the authors' specimens. However the temporal zygomatic, buccal, mandibular and cervical rami (named on the basis of regional supply) were always identifiable. The scheme of origin, however, varied, and to such an extent that eight general types of configuration could be distinguished (Fig. 8 I to VIII). For purposes of convenience in discussion, these were arranged in the order of increasing complexity beginning with the simple type regularly described and figured in anatomical textbooks, and ending with those which exhibited a markedly plexiform arrangement. Between these extremes were placed several groups the selection of which was based upon the number of large anastomoses between branches of one of the two principal divisions of the nerve (preponderantly associated with the temporal portion)¹ and upon the number of anastomoses between the cervicofacial and temporo-facial divisions of the nerve. Some of the anastomoses occurred within the gland others beyond its margins.

Type I (13 specimens, 8 left and 5 right). The basic plan of nerve Type I is simple (Fig. 7 cf. Fig. 8, I). No large unions occur between the various portions of the nerve rami arise in a spray and diverge from the two primary portions

as blades leave the handle of a fan. Within the substance and close to the border of the parotid gland these fibers are, relatively speaking, of considerable caliber (diameter 2.0 mm.). They vary in number from four to six at the point of emergence from the gland. The nerves of the temporal supply emerge from the superior border of the parotid and arch anteriorly and cranially to join the musculature of the ocular and temporal regions. The zygomatic ramus, which often includes the buccal supply courses transversely across the face just above the parotid duct, or crossing it. Either this branch, or more commonly the temporal division, is very large in comparison with the remaining branches. The inferior directed cervical and mandibular rami remain hidden between the two lobes of the gland, to emerge finally from the lower pole. The mandibular branches follow along the body of the mandible, or just inferior to it. It is this branch that several surgeons (Bailey, Adson, and Ott) identify first in preparation for total parotidectomy. The cervical portion passes into the platysma muscle. The single exception to this method of distribution is represented by those specimens of Type II (4 number) in which a component of the buccal supply passes transversely across the maxillary bone on a level with the angle of the mouth. This buccal component is a very slender fiber and is readily found in dissection.

Type II (11 specimens, 5 left, 6 right). A distinguishing characteristic of Type II is the presence of a single anastomosis between various components of the temporo-facial division (Fig. 8, II). In virtually all of the representatives of this group the temporo-facial division quickly splits into two large rami, one directed anterosuperiorly and the other passing anterosuperiorly. The latter soon further subdivides into temporally directed branches to the muscles below the eye and a more transversely directed ramus. The middle and lower rami then anastomose at a point 1 to 3 centimeters beyond the anterior border of the gland from the loop thus formed given off numerous fine twigs to the buccal zygomatic musculatures, and less frequently the temporal region.

In most instances this anastomosis is intimately related to the parotid duct, lying just superior to it. Rarely (2 cases) the communication occurs within the substance of the gland. From the connecting stem spring the temporal and zygomatic rami, which (as in Type I) are already separated as they pass from the border of the gland. Most frequently (one instance) the intraparotid loop passes around the superficial temporal artery

¹A fact first noted by Turella (1931).

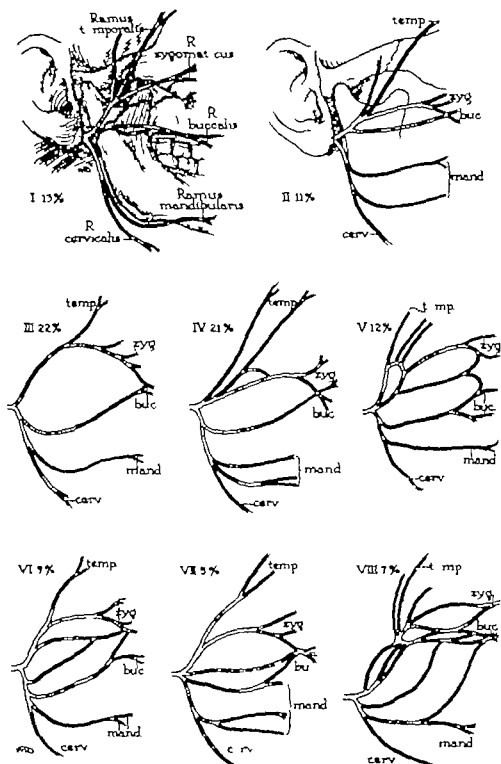

Fig 8 Major types of facial nerve branching and anastomosis. I Major divisions (temporal and facial) independent II anastomosis between ramal of the temporal division III connection between adjacent ramal from the major divisions IV anastomoses representing a composite of those in II and III V proximal anastomosis within the temporal component, distal interconnection between the latter and the cervical component VI, two anastomotic ramal sent from the buccal division of the nerve, contributing to the zygomatic part of the temporal VII transverse ramus from the trunk of the nerve, contributing to the buccal ramus formed by anastomosis between the two major divisions VIII richly plexiform communications, especially within the temporal portion of the nerve.

vein. The inferiorly directed branches in specimens of Type II are similar to the corresponding rami of Type I.

Type III (22 specimens, 9 left, 13 right) This is the third of the groups in which the pattern of configuration of the nerve is of basic character. In the scale of ascending complexity it represents the first intermingling of elements derived from both of the primary divisions of the nerve, namely the temporofacial and cervicofacial portions (Fig 6 and Fig 8, III). A slender trunk arises from the cervicofacial division very quickly after its origin from the main nerve (within 1.5 cm.) and passes superiorly in an oblique course to anastomose with a strong, arching continuation of the temporofacial division (Figs. 1 to 3). In all instances the anastomosis is extraglandular occurring most frequently 1 to 3 centimeters beyond the anterosuperior extremity of the gland. In most instances the anastomosis occurs immediately over the parotid duct, just before the latter passes deeply to pierce the buccal muscles.

In an exceptional specimen (Figs. 1 and 2) the contribution from the cervicofacial division was formed by the union of several filaments.

Type IV (21 specimens, 11 left, 10 right) Type IV is essentially a composite of the two preceding patterns. There is an anastomosis between the temporal and zygomatic subdivisions of the main superior trunk as well as one between the superiorly directed ramus from the cervicofacial division and a strong branch from the zygomaticobuccal supply (Figs. 4 and 5 and Fig 8 IV). In 6 cases the anastomosis occurring within the temporofacial portion of the nerve was intraglandular while in the remaining 15 the union occurred beyond the anterior border of the parotid. In 20 cases the anastomosis between the two principal divisions was extraglandular i.e. having relationships similar to those obtaining in Type III. In the remaining single instance the anastomosis lay between the two leaves of the gland. The latter was the only case among the representatives of Type IV in which both of the anastomoses were entirely intraglandular.

Type V (12 specimens, 6 left, 6 right) In specimens belonging to this group one characteristic feature is the presence, in the temporofacial division of the nerve of two large anastomoses (Fig 8 V). The proximal loop is very small and intraglandular. It is usually about 1.5 centimeters in diameter and often encloses the temporal artery and vein. From it arise three major components: small temporal filaments to the muscles at the orbit; a heavier superior branch to the zygomatic musculature; a smaller some-

what inferior branch which forms a second loop by joining the preceding over the parotid duct at a point 1 to 3 centimeters distal to the anterior pole of the gland. As the second of two characteristics, this third component is reinforced by an anterosuperior contribution from the cervicofacial division (within a distance of 1 cm. from its origin in the main trunk of the nerve). In this way the two main components of the nerve are brought into anastomotic connection. From this distal loop, formed by junction of the two main divisions, small filaments pass the musculature above the angle of the mouth. In only one instance is lower communication was entirely intraglandular; in the remaining 11 the cervicofacial contribution passed beyond the margin of the gland below union.

Type VI (9 specimens, 3 left, 6 right). The pattern in Type VI is the converse of the preceding, in that the arrangement of major and minor loops is reversed. One variable anastomotic loop occurs between rami of the temporofacial division (Fig 8 VI). In 5 cases, it was relatively small and entirely intraglandular as in the case of the proximal loop in Type V. In 2 cases it extended less than 2 centimeters beyond the anterior border of the superior portion of the gland. In the remaining 2 (of the total 9) it extended approximately 1 centimeter beyond the border. Additionally Type VI possesses two anastomotic filaments which pass from the cervicofacial division to intermingle with elements of the temporofacial portion. In 2 instances, these branches arose by a very short common trunk from the cervicofacial division, approximately 1 centimeter beyond the latter's origin. In the remaining 7 a proximal ramus arose about 1 centimeter from the main bifurcation, and a second one was given off at a distance of from 2 to 3.5 centimeters beyond the bifurcation. In 3 cases the latter branch crossed the angle of the jaw. In all instances the ramus which arose from the inferior division joined the same transversely directed branch, in succession, 1 centimeter apart to form an arcade with a small so that the additions gave the appearance of reinforcing it. From the distal loop, which usually lay over the anterior border of the masseter muscle, numerous small filaments passed to superior labial and zygomatic musculature.

Type VII (4 specimens, 1 left, 3 right). The seventh type, while not strikingly complex, was the least common configuration encountered in the entire investigation. It is very similar to Type III in that anastomosis occurs between a strong transverse branch of the temporofacial

Fig. 9. Types of parotid gland, recording variations in form and size. Star in each indicates the site of the external angle of the mandible.

division with a smaller ascending ramus of the cervicofacial portion of the main nerve (Fig. 8 VII). The unique feature is the presence of a central branch arising from the main trunk of the nerve and passing transversely to join the above mentioned anastomosis. In this way a third element is contributed to the primary anastomosis. From the anastomosis formed by the union of three branches numerous terminal filaments arise to supply the musculature between the lower eyelid and the angle of the mouth. The anastomosis bears the usual intimate relationship to the parotid duct but the point of union is usually situated just inferior to the duct.

Type VIII (7 specimens, 3 left, 4 right) Specimens in this group are characterized by the presence of richly plexiform intercommunications (Fig. 8 VIII). None has a strong transverse branch such as was so commonly present in specimens belonging to the other groups. From 4 to 7 intercommunications occur within the nerve itself most often between the two main divisions. What the individual rami lack in size they make up for in number and in frequency of intercommunication. A second striking feature is the presence of small triangular masses of fibrous tissue which occurs between adjacent branches of a nerve. Two of these were found at the first or second branchings of the temporofacial division. They were firmly attached and appeared to be an integral part of the main nervous structure. It is the authors belief that the presence of such a plexiform arrangement is responsible for the

partial successes reported by Duval and Redon (1932) who removed the cervicofacial portion of the nerve in the course of total parotidectomy¹

B. Parotid Gland

The parotid gland is an organ of variable form. Despite this fact the variations can be rather satisfactorily classified (Fig. 9). In addition to the criterion of size, there is that of relative bulk of the superficial and deep portions as discussed by other authors (Grégoire 1912; McWhorter 1917). This relationship is also variable since the deep lobe may be merely a small button of glandular tissue, or may come close to equaling in size its overlying superficial lobe.

The features of form and size were combined in studying 76 glands. The main grouping was made on the basis of form while subgroups were based upon size. The larger glands (those longer than 6 cm.) extend for a distance of several centimeters into the neck just anterior to the ventral border of the sternocleidomastoid muscle—a fact which is of surgical interest.

Length of gland varies between 4.5 and 9.2 centimeters (average, 6 cm.) while the width varies between 2 and 5.4 (average 3.3 cm.) More than half of the glands (40 specimens or 52.6 per cent) fall into a group for which a conventional textbook description would be suitable: they are triangular in shape, largest at the superior extremity and narrowing gradually to a blunt apex.

¹In 5 cases, patients had mouth droop, and had some involvement of the eye; the other 3 were esthetically successful.

pointing inferiorly. Within this inclusive group are two subgroups: the first is made up of small glands (21 in number) whose average length is 5.1 centimeters, and whose average width (at superior pole) is 3 centimeters (Fig. 9, A¹); the second is made up of glands with average length and width of 6.6 centimeters and 3.4 centimeters, respectively (Fig. 9, A²).

In the second major group (24 glands or 31.5 per cent of the total) the gland is not constricted below but maintains a uniform width throughout its length, with superior and inferior poles gently rounded. Here, again, subdivision on the basis of size can be made: a larger lot (13 specimens) with average length of 5.3 centimeters and an average width of 3.6 centimeters (Fig. 9, B¹); a smaller lot of bulkier glands, averaging 6.5 centimeters in length and 3.5 centimeters in width (Fig. 9, B²).

In the third of the main groups (6 specimens) the glands have the form of an inverted letter L (Fig. 9, C); they are almost as broad at their superior extremity as they are long. The average length of these is 5.7 centimeters, while the average width is 4.7 centimeters. The transverse portion of the L, represented by the superior portion of the gland, is made up of glandular tissue which lies along the superior border of the main parotid duct (in 1 instance reaching a length of 5.4 cm.). In all but 2 instances, this glandular tissue was associated with the superficial lobe of the gland. In the 2 exceptions, the tissue was on the same plane as the deep lobe and appeared to be part of it.

In the fourth, and last, category (6 specimens) all of the glands are large, with an average length of 6.7 centimeters, and an average width of 3.7 centimeters. The glands are roughly triangular in outline, but the broad base of the gland forms the inferior pole of the gland; the superior pole then being represented by the rather sharp apex of the gland (Fig. 9, D).

Accessory glandular masses are fairly common: 16 small nodules of tissue occurred in 15 of the 76 cases (19.7 per cent). They are invariably situated superior to the main parotid duct; sometimes partially overlapping it (Fig. 6). Although an accessory gland may be located anywhere between the anterior border of the main gland and the anterior border of the masseter muscle, in the majority of instances they are found along the proximal one-half of the duct. In length the accessory glands vary from 1.0 to 2.3 centimeters (average 1.4 cm.). In width, from 0.5 to 0.8 centimeter (average, 0.7 cm.). The long axis always corresponds to that of the main duct into which

the accessory element empties by a very short, slender duct.

Regarding the main duct of the parotid gland, it may be said that if it drains the upper portion of the gland, its course will be transverse across the masseter muscle (Fig. 1). Of the glands studied the duct pursued this course in 42 specimens, a fact which means that in these cases it was in early close association with the nerve (Fig. 1). When the duct drains the central or the lower portion of the gland, it tends to pass obliquely to the mouth (Fig. 4). Such a course was found in 32 cases. In 3 specimens "double" ducts occurred (Fig. 6). One component drained the superior portion of the gland and passed transversely with an inferior component drained the lower glandular tissue and coursed obliquely upward. A connection occurred between the two elements 1.5 to 2 centimeters beyond the anterior border of the gland.

CONCLUSIONS

So intimate is the relation of the facial nerve to the parotid gland that the scheme of nerve ramification and intercommunication can be most satisfactorily presented on such basis. In fact, the pattern of anastomosis seems to be governed by the shape and position of the deep lobe of the gland, and by the presence of an isthmus of tissue between the latter and the larger superficial portion.

Although the parotid is subject to considerable variation in size and form, it is invariably bilobed. The small deep lobe overlies the condyloid and coronoid processes of the mandibular ramus; it is likely to be ovoid in outline. The large, superficial, lobe, which conceals the lesser lobe, is usually triangular in outline, with the narrow, bluntly apical, portion more frequently directed downward than upward.

Now as the trunk of the facial nerve comes toward the surface, through the space bounded by the mastoid process of the temporal bone and the condyloid process of the mandible, it insinuates itself between the lobes of the parotid gland, in close relation to the isthmus. Thereupon it divides quickly, the divisions appearing as the divergent arms of the letter Y: one division ascends obliquely toward the temporal region while the other descends obliquely into the cervical region. Both of these divisions, and the proximal portions of the branches, are usually covered by the superficial lobe of the parotid; the divisions skirt the corresponding margins of the isthmus, and usually anastomose distally to surround and clasp it. Whether the divisions continue independently or, by conjunction, are circumferential to the isthmus,

they tend to converge as they proceed forward—slightly in the first instance strikingly in the second. In those cases in which the temporal division joins the cervical (76 per cent of specimens) the fusion occurs in such a way that the buccal branch appears to be the continuation of the confluent portions. The buccal branch is somewhat superior to the main trunk of the nerve (by a finger's breadth or less commonly), and even when the superficial lobe of the gland is prolonged forward this branch is likely to be exposed just beyond the parotid tip. It regularly overlies the parotid duct.

When the divisions remain separate the branches of the temporal portion spread out like the spokes of a quadrant of a wheel: those of the cervical portion on the contrary leave the division as if they were twigs derived from one side of a branch—the division itself continuing still a prominent branch, into the neck. When on the contrary, the divisions anastomose, the temporal, zygomatic, buccal and some of the mandibular branches, quit the loop centripetally in series—the lowermost mandibular branch at least, appearing to be a branch of the descending cervical division, not as a derivative of the loop. Just as there exist variations in the brachial or in the lumbosacral plexus of nerves, here also there are aberrancies in pattern of cords and nerves. In about 65 per cent of the cases in which anastomoses occur (76 per cent of the total number) the branches originating from the anastomotic loop are temporal, zygomatic and buccal; in the remaining 11 per cent some mandibular branches are included. This means that in the cranial two-thirds or three-fourths of the entire parotid zone the related nervous elements are likely to be involved in a plexiform scheme. In most instances the forming elements of the plexus are largely extraglandular.

Secondary anastomotic loops are fairly common, and may be either proximally or distally placed. In rare instances the space enclosed by anastomosis of the two regular divisions (temporal, cervical) of the facial trunk, may be bisected by a third division: this transverse supernumerary division would seem to be principally buccal, since it reaches the distal (anterior) margin of the loop at the customary point of origin of the nerves destined for the rima oris.

From this anatomical study certain features of a practical significance are made evident, these may be considered in the order in which they would affect the mode of surgical exposure. The parotid fascia should be opened posteriorly and reflected forward from a preauricular incision in order to expose the anterosuperior or apical por-

tion of the parotid gland. Since the gland usually possesses the outline of an inverted triangle, with the base represented by the part of the superficial lobe which coincides with the line of the zygomatic arch, exposure of the gland along its superior margin will lead the operator to its tip. When the apex has, by this maneuver been uncovered the parotid duct and the associated buccal branches of the facial nerve can be readily identified, since the duct either extends forward from the apex or lies just inferior to it. Next, employing the buccal ramus as a guide to the more proximal position of the large temporal division of the nerve, or of the point of anastomosis of the latter with the smaller cervical division, the radially directed nerves can be safely exposed in serial succession backward by progressively lifting the margin of the gland. In this process the isthmus, which connects the superficial and deep lobes, will serve as a pedicle and as a core round which the two divisions course. By tracing the large upper division dorsalward toward the ramus of the mandible, the operator will be guided to the main trunk of the facial nerve. Therefrom the small lower division can be followed along the inferior margin of the isthmus and downward toward or into the neck. Having thus reached an area where the divisions and rami are strongest and their patterns of branching least complex, glandular tissue may be excised with minimal danger to the facial nerve.

Because the parotid gland is sometimes small or is so formed as to be constricted cranially, more than the regular fraction of the main divisions may be apparent beyond the periphery of the parotid. Obviously when such an arrangement obtains special care must be exercised if the branches are to be spared trauma or transection.

SUMMARY

A study of the facial nerve, especially in relation to the parotid gland, was conducted in 100 carefully prepared dissections of adults.

From the data collected (in the form of artist's drawings and authors' sketches) the bilobed nature of the parotid gland was definitely established as was also the regular position of the facial nerve between the two glandular portions, namely, superficial larger part and deep smaller portion.

From examination of the collected records of facial nerve ramification it was found that all could be conveniently and graphically catalogued as belonging to one of a total of eight types, in which those with anastomoses between major divisions or between branches of either of the latter outnumbered the nonanastomotic types in

the proportion of 3:1. It was also learned that in the specimens where anastomosis took place, the loop thus formed surrounded the isthmus of the parotid gland.

The types were illustrated by diagrammatic drawings from actual specimens and detailed drawings, from similar source were secured to portray the relationship between the nerve's divisions and branches to the lobes of the parotid gland.

On the basis of the morphological conclusions, some opinions are expressed on importance of the observed facts to procedure in extirpation of the gland. These deal with the manner of reflecting the superficial parotid lobe, the resultant exposure of all larger nervous elements, the existence of an area where nerves are concentrated the service

ability of identifying the common relationship of the buccal component to the parotid duct.

CAUSALGIA

FRANK H MAYFIELD M.D. F.A.C.S., Major M.C., A.U.S., Cincinnati Ohio and

JOHN W DEVINE, M.D., F.A.C.S. Captain M.C., A.U.S., Lynchburg Virginia

THE term causalgia was used in 1865 by Mitchell Morehouse and Keen to describe a bizarre syndrome resulting from injuries to peripheral nerves. Its cardinal features are the subjective complaint of burning pain in association with trophic and vasomotor changes in the injured extremity. The pathology and pathogenesis of causalgia are unknown. Indeed there is some confusion as to what constitutes a case of this condition. Some writers (1, 2, 4) believe that causalgia is atrophy, painful osteoporosis, and other so called "minor causalgias," and indeed painful phantom limb are different clinical manifestations of the same underlying disorder. The similarity however is remote and we are of the opinion that causalgia varies sufficiently in severity to be considered a clinical entity.

In this paper we will present the data from 15 cases, in which the symptoms and objective findings were of sufficient severity to compare with those described by the original authors. These cases have been studied to correlate subjective and trophic changes with blood flow in the part. Blood flow was determined by means of the oscilometer, skin temperature readings, and at times the histamine flare test. In addition all patients have had psychiatric examination because of the belief by some that predisposing constitutional psychic factors play an etiologic rôle. The effect of interruption of the sympathetic chain with procaine block and by surgery, and the effect of hyperthermia have been observed.

These studies suggest that the pain of causalgia does not result from alteration in the blood flow. For some patients are found in whom the injured extremity is in a state of vasodilatation while others show vasoconstriction. The trophic changes and the response to heat and cold vary considerably with the blood flow. The severity of trophic changes increases with prolongation of symptoms.

MATERIAL

The 15 cases were encountered in a group of 100 peripheral nerve injuries (2¹). The median nerve (6), ulnar (5), radial (3), peroneal (3), and sciatic (2). The patients were treated by the following: 1. Physical therapy, 2. Procaine block, 3. Sympathectomy, 4. Amputation, 5. Prosthetic, 6. Psychological, 7. Combination of two or more.

was involved in 7 cases, the median and ulnar in 1, the brachial plexus (median and lateral cords) in 1. The sciatic nerve was involved in 6 cases. In each instance the wound was of a penetrating type due to bullet or shell fragment and was proximal to the elbow or knee. Two patients were officers, 13 were enlisted men. Their ages ranged from 23 to 33 years. The wound became infected in 2 cases. Sizeable foreign bodies were retained at the level of the injury in 3 cases. The nerve lesion was incomplete in each instance. This syndrome has not been seen in any individual in whom the nerve was completely divided. No patients have had any major vascular injuries. Three of the patients had also suffered a concomitant fracture of the femur.

SYMPTOMS AND SIGNS

Mitchell Morehouse and Keen noted that the onset of burning pain was usually late, at times being delayed as much as 1 to 2 months. They observed that pain was always present in the distal part of an extremity, usually in the palm or in the dorsum of the foot, and not confined to the autonomous zone of the injured nerve. They commented that certain patients had warm skin and others cold but placed greater stress on the glossy, shining skin and loss of hair, etc., and considered that these changes would appear in all cases of long duration.

In 9 of the 15 cases here reported the burning pain was present from the moment of impact. In 3 others it appeared within 24 hours. In 3 it was delayed as long as 3 weeks. The pain was of intense burning character and varied in intensity with emotional stimuli such as anxiety, anger, or fear. Noises such as the scraping of a chair, the tearing of paper, loud music, or breaking glass caused intense suffering. Lighting the room without warning would often provoke a severe paroxysm of pain.

Eleven of the 15 patients obtained some relief from the application of moisture. It was Mitchell's (6) opinion that moisture was the factor which afforded comfort rather than the temperature. Nine of our patients preferred cold water, 2 obtained some relief from warm water, and in 3 cases the effect of moisture was not significant. Throughout

the proportion of 3:1. It was also learned that in the specimens where anastomosis took place, the loop thus formed surrounded the isthmus of the parotid gland.

The types were illustrated by diagrammatic drawings from actual specimens and detailed drawings, from similar source, were secured to portray the relationship between the nerve's divisions and branches to the lobes of the parotid gland.

On the basis of the morphological conclusions, some opinions are expressed on importance of the observed facts to procedure in extirpation of the gland. These deal with the manner of reflecting the superficial parotid lobe, the resultant exposure of all larger nervous elements, the existence of an area where nerves are concentrated, the service

ability of identifying the common relationship of the buccal component to the parotid duct.

Nine of our patients preferred cold water, 3 obtained some relief from warm water and in 3 cases the effect of moisture was not significant. Throughout

TABLE I.—SUMMARY OF CASES

Case Age	Injury	Duration	Onset	Relief from measures	Blood flow	Treatment	Result
1. F.H.M. 20	Bullet, left thigh	3 mo	Immediate	Warm	Reduced	Sympathectomy lumbar L3-4	Relief
W.W.D. 24	Shell fragment, left thigh	3 mo	Immediate	Cold	Increased	Sympathectomy lumbar L3-4	Relief
3. L.C.K. 3	Bullet, right arm	mo	Immediate	None	Increased	Sympathectomy dorsal, 8th, 9th and 10th	Relief
4. J.G. 28	Bullet, right shoulder	3 1/2 mo	Immediate	None	Increased	Temporary relief after procaine block	Relief
5. A.B. 3	Bullet right arm	7 mo	24 hours	None	Increased	Temporary relief after procaine block	Relief
6. J.U. 23	Shell fragment left thigh	3 1/2 mo	24 hours	Warm	Reduced	Fever therapy 3 weeks	Relief
7. G.T. 27	Bullet, left thigh fractured femur	mo	3 weeks	Cold	Increased	Sympathectomy lumbar L3-4	Relief
8. G.L. 27	Shell fragment left thigh; fractured femur	mo	3 weeks	Cold	Increased	Sympathectomy lumbar, L3-4	Relief
9. D.C. 3	Shell fragment left thigh; fractured femur	8 mo	hours	Cold	Increased	Sympathectomy lumbar L3-4	Relief
10. K.S. 20	Shell fragment left arm	mo	Immediate	Cold	Increased	Sympathectomy lumbar L3-4	Relief
J.L. 4	Shell fragment left arm	mo	Immediate	Cold	—	Sympathectomy dorsal, preganglionic	Relief
11. B.G.	Bullet, right arm	24 hr	Immediate	Cold	—	Sympathectomy dorsal, preganglionic	Relief
12. K.M. 20	Bullet, left arm	mo	Immediate	Warm	Reduced	Sympathectomy dorsal, preganglionic	Relief
14. R.S. 26	Bullet, left ankle	mo	3 weeks	Cold	Increased	Sympathectomy dorsal, preganglionic	Relief
15. R.B. 24	Shell fragment right arm	mo.	Immediate	Cold	Increased	Sympathectomy dorsal, preganglionic	Relief

*Prior to neurolysis, warm water afforded relief; after neurolysis cold water afforded relief.

†Spontaneous recovery but hyperaesthesia to cold.

‡Wound high, right thigh. Removal lumbar ganglia 3 & 4 produced no relief. Removal lumbar ganglia 2 followed by caustic relief.

the course of the disease, in our cases, the patients demands for cold or hot water did not change except in 1 instance. In Case 2 intense burning pain developed from a partial lesion of the left sciatic nerve above the knee. For 3 1/2 months after injury at which time neurolysis was done, warm water had afforded some relief. Thereafter warm water was painful but cold water caused marked lessening of pain and the patient kept the foot immersed in iced water until it was necessary to withdraw it, to prevent vascular damage.

Three patients kept their hands constantly covered with a wet cloth. Another (Case 11) maintained a basin of water at his bedside (Fig 1) for this purpose. Without exception, the patients exercised great care to prevent the part being touched, particularly by rough objects. One (Case 4) kept the hand protected constantly in dry flannel (Fig 2). Most patients would go to what appeared to be absurd extremes to prevent motion of the part. Some would grasp the painful

extremity just proximal to the wrist or ankle with the normal hand, and hold this position for hours. The facial expression usually reflected intense suffering (Fig 3).

In the more severe cases the patients were poorly nourished due to low food intake, and were irritable and shut in, showing no interest in family or friends even though they had been overseas for many months. They preferred to be alone in a darkened room. They were unduly critical of attendants. The case histories in most instances revealed items of information such as these, which suggested that the disorder might be entirely psychogenic in character. Mitchell stated that the word "hysterical" seemed to describe the state best.

The motor and sensory loss was difficult to determine for usually the patient refused to move the part or permit it to be touched. In addition, there was usually marked stiffness of the joints, due to disuse.

Fig. 1 Case 11. Photograph shows method devised by patient to keep hand constantly wet.

The trophic changes were generally of two types. In the first type of which we have had 3 cases the skin was cold, thin and glistening, the superficial layers were denuded and sweating profuse. With this there was loss of hair, tapering of the digits and a tendency of the nails to curl. Oscillometric examinations showed marked vasoconstriction as compared to the opposite extremity and the skin temperature was from 2 to 6 degrees lower than in the normal limb. The pain was lessened by application of warm water. One case of this type (Case 1) developed intercurrent malaria (*Plasmodium vivax*). During elevation of temperature he was completely free of pain. This was true with each of the three chills. The pain returned when the malaria was controlled. An additional case (Case 7) was given three bouts of artificial fever therapy, each of 3 hours duration with a tem-

Fig. 2. Makeshift protective covering of dry flannel constantly worn.

Fig. 3 Case 5. Photograph showing facial expression and the patient immobilizing the painful member by holding it with the other hand.

perature of 104 degrees. Pain disappeared immediately with the elevation of temperature and returned in mild form with the fall of temperature after the first two bouts. There was no return of pain after the third.

In the second and more frequent type (9 cases) the skin of the painful part was warmer than that of its opposite member and the hair long and coarse (Fig. 4). The skin was relatively dry and at times actually scaly. In three instances the skin was smooth but was not comparable to the glossy skin of those in vasoconstriction. These patients experienced relief from cold water and the pain was exaggerated by application of heat, either moist or dry. One patient (Case 8) who was placed in a fever cabinet experienced such severe pain that he had to be removed within less than 1 hour. Oscillometric examination on these patients, when it could be done, showed the involved extremity in vasodilatation. The skin temperature of the painful part was from 2 to 5 degrees warmer.

Fig. 4 Case 4. Excessive hair growth is present in causalgic limb.

Fig. 5. Spotty osteoporosis of the small bones of painful right foot

The severity of the trophic changes increased with the duration of symptoms, yet the types seemed unchanged.

In 3 cases, oscillographic and skin temperature studies were not carried out

OSTEOPOROSIS

In 9 cases the extremities were examined roentgenographically for evidence of osteoporosis. As has been demonstrated by Miller and de Takats, there was spotty osteoporosis of the small bones of the hands and feet in each case with vasodilatation (Fig 5). If the duration of the illness was long extending more than 3 months, the demineralization tended to become generalized. The 3 patients who showed vasoconstriction also showed demineralization of the painful part, but it was not spotty.

TREATMENT

Success has been reported with many forms of treatment in causalgia. Mitchell, Morehouse and Keen used leeches. Direct surgical attack on the nerve trunk above, below and at the level of injury is reported to relieve the syndrome at times. Varying degrees of success have been reported with drugs and physiotherapy. Interruption of the sympathetic chain has consistently been the most efficacious procedure.

Of our cases, one was relieved by fever therapy and two recovered spontaneously. The remainder

were treated by interruption of the sympathetic chain. Every patient had repeated procaine block of the appropriate chain. The least number of injections given to one patient was 3 and some patients have had as many as 8. The relief following injection was dramatic. It was instantaneous and absolute, and usually was maintained for intervals of from 1 to 3 hours, after which the pain returned reaching its maximum intensity within a short while. We have not been able to provide any lasting benefit by this procedure, and have subsequently interrupted the sympathetic chain with surgery. Despite this brief period of complete relief the patient almost invariably objected to repeating the procedure because of fear of being stuck.

Cervicodorsal sympathectomy was done on 1 case in which the arm was involved, the stellate and second dorsal ganglion being removed. Six cases with arm involvement were treated by preganglionic ramisection.

In 5 of the 6 cases in which the leg was involved, the 2d, 3d and 4th lumbar ganglia were removed. Four were entirely free of pain upon awakening from the anesthetic and have remained well to this date. In 1 case (Case 8) removal of the 3d and 4th lumbar ganglia only was done at an initial operation because of technical difficulties, and pain persisted. Subsequently the 1st and 2d lumbar ganglia were removed, with complete relief.

Neurolysis was done in 5 cases, and periaxillary sympathectomy at the level of the injury in 3. The pain was not influenced by these procedures.

It was impressive to observe the remarkable change in the patients' attitude and behavior following relief from pain. Without exception they became pleasant, co-operative, and happy, and showed interest in their families and friends. In several instances the recovery of function after sympathectomy was rapid, suggesting that reflex paralysis was present. In many the nerve injury was mild and the ultimate recovery after sympathectomy was good. Each patient in this series, however, was left with a rather marked hyperesthesia in the autonomous zone of the involved nerve. During the period of pain the patient would not move the part and the joints stiffened rapidly. In the majority of instances this was the chief residual disability. The stiffness was more marked in those cases of long duration.

PSYCHIATRIC ANALYSIS

Each patient of this group was submitted to a psychiatrist for examination after being relieved of the pain and each one was classified as a nor-

mal individual with a stable personality. Six patients were returned to duty. 4 were discharged for residual disability of the injured nerve but without pain. Five are still under observation.

ANALYSIS OF STUDY

The material on which this paper is based is not sufficient to permit final conclusions. It is possible that additional observations will show that the trophic changes are not always consistent with the alterations in blood flow as we have observed. It is also possible that the blood flow in a causalgic limb may vary from time to time, but this has not been observed.

The permanent relief of pain which accompanies interruption of the sympathetic chain suggests that the mechanism of relief is by interruption of an afferent pain pathway. The relief of pain which accompanies the application of warm or cold moisture distal to the injury and the relief accompanying hyperthermia however is not consistent with this argument and is not understood.

The personality changes always present during the painful stages are secondary to the pain. There is no evidence in our cases that there is a predisposing constitutional psychic factor.

SUMMARY AND CONCLUSIONS

In a study of 15 cases of causalgia the following observations were made:

1. Burning pain is a constant complaint and is usually immediate in onset.
2. The median or sciatic nerve was involved in each instance and the lesion was incomplete.
3. Certain patients showed vasoconstriction in the causalgic limb others showed vasodilatation.
4. The trophic changes and response to warm or cold moisture and to hyperthermia varied depending upon the blood flow.

5. Twelve patients were relieved by sympathectomy of the involved limb. 1 was cured by artificial fever therapy and 2 recovered spontaneously.

6. Further observation as to the value of fever therapy will be made.

7. Direct surgical attack (neurolysis) upon the injured nerve which was performed on 5 cases and penarterial sympathectomy at the level of injury performed in 3 have not been of benefit.

8. Procaine block of the sympathetic chain affords complete relief temporarily and should be repeated 2 to 3 times, although no case in this series has had any lasting benefit from this procedure.

9. Sympathectomy (preganglionic) gave immediate and lasting relief to 12 patients.

10. The site of injury must be included in the sympathectomy.

11. Sympathectomy should be done early to prevent stiffness of joints due to disuse.

12. The personality changes always present during the painful stages are secondary to the pain. There is no evidence in our cases that there is a predisposing constitutional psychic factor in causalgia.

A SAFE SIMPLE AND EFFICIENT METHOD OF INTESTINAL ANASTOMOSIS

J PEYTON BARNES M D F A C S Houston Texas

NO one single method solves the problem of how best to do an intestinal anastomosis. Many fine methods, some extremely ingenious, have been described and all have their good points and probably all are equally efficient in hands trained to use them. Most require specially designed instruments in addition to special skill in the use of these instruments.

However it is one thing for an expert surgeon thoroughly trained and adequately equipped to elect to do a resection and anastomosis, and for an unskilled surgeon who operates only occasionally to be suddenly confronted with the necessity of doing one as an emergency. Many emergencies require resection and many such cases are handled by surgeons neither trained nor equipped to do a resection. It seemed to me that if a method of anastomosis could be worked out whereby only the ordinary instruments found on the usual hospital tray were necessary many more surgeons might be able to make use of it. The method to be described was therefore devised. The operation can be readily carried out with the use of only standard hospital instruments. The method is almost fool-proof even for those of little training if the steps are carefully carried out. Recently Stevenson and Totten have published descriptions of two other methods designed probably with the same thought in mind careful study of these articles is recommended.

TECHNIQUE

Instruments Either long Kocher or straight Ochsner hemostats are used. I use two long Ochsner hemostats with the end teeth filed smooth (Fig. 2 insert) although this is not essential. A small rubber tubing screw clamp is used to hold the forceps together (Fig. 6 insert, A) while the anastomosis is completed. This clamp is found in every hospital intravenous set and does not have to be of the design shown here any small tubing clamp will do. A few curved Kelly or mosquito hemostats are useful. No. 0 chromic catgut sutures on straight atraumatic intestinal needles are used. For the outside or last row of sutures, a long

thread with an atraumatic needle on each end is useful but not essential.

Procedure. Step 1. The segment to be removed is determined, and the lines of section are chosen. At these two points a blunt hemostat is pushed through the mesentery and a hole is made which is enlarged toward the diseased segment (Fig. 1). Enough mesentery is denuded so that the area for anastomosis will be mesentery free. The hemostats (crushing) are so applied that the mesenteric border comes to the center of the crushed area, not at one end of it. The hemostat therefore is applied at right angles to the mesentery (Fig. 2) not parallel to it. Totten is, I believe the first to describe this step and deserves credit for so doing, but I have been using it for some time. Two heavy straight hemostats are also placed on the diseased segment, which is then cut away with a cautery as usual. We now have the situation as shown in Figure 2.

Step 2. With a straight intestinal needle, a through-and-through suture is placed across the end of each bowel end (Fig. 3). This suture passes through and through from side to side, just as closely below the hemostat as possible but does not pass over it. It is most convenient for the operator holding the hemostat in his left hand, to start the suture at the end of the hemostat and sew toward the handles. The first and last bites must be taken in the very edge of the bowel itself. Each bowel end is so treated.

Step 3. Each hemostat is taken off (Fig. 4) and carefully reapplied (Fig. 5) so that its tip end is not quite level with the edge of the bowel wall (Fig. 5). The hemostat is reapplied in the original crushed area and its tip must catch the end of this first suture which is cut short after being caught in the end of the hemostat (Figs. 5, 6). The reapplication of the hemostat is an important step.

Step 4. The hemostat blades are laid side by side and held together with the screw clamp (Fig. 6). To avoid having any space between the distal ends of the hemostats, a small piece of metal bent on one end (Fig. 6 insert, B) is used to pry the handles apart. A sterile tongue blade, always available, will serve the same purpose. If the hemostat blades are long enough the screw clamp

Fig. 2. Diseased portion removed. Crushing hemostats are placed at right angles to mesentery. Note ends of hemostat projecting slightly beyond bowel walls. The insert shows ends of Ochsner hemostat filed smooth.

can be applied distal to the lock, thus making possible exact approximation of the blades. Like Totten I had had a special holding device prepared but this simple screw clamp is far superior. The operation can be done without the use of the screw clamp but with it the procedure is materially simplified.

Step 5 Suturing is now begun. Interrupted mattress sutures are used, the first being placed so as to cover the ends of the hemostat. Unless the hemostat has been pulled back and reapplied as described in Step 3 the ends would have to remain protruding. These mattress sutures are placed about halfway up the clamps (Fig. 6) and tied (Fig. 7).

Step 6 At this point the hemostat is rotated 180 degrees, and half of the posterior side is likewise treated (Fig. 8).

Step 7 The hemostat is rotated back to its original position, the screw clamp is removed both blades of the hemostat are loosened and pulled back enough so their ends are only halfway across the crushed area and just under the last tied stitch. They are then reapplied and the screw clamp again put on (Fig. 9).

Step 8 The anterior row of sutures is now completed the hemostat rotated again and the posterior row also completed. As the last mattress suture is made ready to tie the clamp and hemostat are loosened and pulled out completely (Fig. 10).

Step 9 With a long thread of No. 0 chromic and anatraumatic needle on each end a running suture is placed completely around the anastomosis. This row of sutures is started at the point where the short ends of the first sutures are located half of the suture material being used for the anterior half for the posterior layer (Fig. 11). This is tied

Step 10 The original through and through sutures across both bowel ends are now grasped by the long ends, which were left uncut when inserted and are pulled out. Until these sutures are pulled out no spillage from either bowel end could occur accidentally even if the bowel end should pull out of the holding forceps as occasionally occurs.

Fig. 7a.

Figs 6a to 7a, inclusive, show method of anastomosis by using continuous suture for the first layer mattress sutures for the second

Fig. 6 Placing of anterior sutures. The first stitch

should cover ends of clamps. Not a screw clamp is placed. The clamp locks, and use of edge between handles eliminates space between clamp blades. Insert shows clamp and edge

Fig. 7 First half of anterior row completed.

Sutures must be placed deeply enough to catch the submucous layer. Failure to do this may and often does result in leakage. When the needle point is placed deeply enough as the suture is started the bit of tissue over it is white and blanched as upward pressure is made. If one can see the needle point all the time it is not deep enough.

Some prefer to use a running stitch as the first row instead of the interrupted mattress sutures. This is very easy to do with this technique and is shown in Figures 6a, 7a, 8a, 8b, 9a, 10a, and is

somewhat faster. I would call attention at this point however to the very great importance of placing the interrupted mattress sutures first. By so doing the danger of any pursestring effect is obviated. When the running suture is used as the first row the pursestring tendency which develops as the suture is drawn taut is difficult to prevent. The method recommended offers considerable protection against this tendency to contract and reduce the diameter of the anastomosis.

Several steps of prime importance are worthy of mention

Fig. 8.

Fig. 9a.

Fig. 9b.

Fig. 9c.

Fig. 9d.

Fig. 10.

Fig. 10a.

Fig. 11.

Fig. 8 Hemostat is rotated first half of posterior row of sutures is placed and tied.

Fig. 9 Hemostat has been rotated back to original position loosened pulled back so that ends are just under last tied anterior stitch, reappled and rest of anterior row of sutures is placed and tied. Hemostat is then rotated again

to position as in Figure 8 and rest of posterior row is completed, after which hemostat is withdrawn completely

Fig. 10 First row of sutures is completed. Note the two original through-and-through sutures still in place. They can be removed now or after the running stitch is placed

Fig. 11 Placing of the last row of sutures, continuous.

1 The hemostats are so applied that the mesentery comes to the middle of the hemostat

2 The portion of bowel to be used in the anastomosis must be denuded of mesentery

3 A through and through suture in each bowel end, if used as described absolutely prevents any accidental spill at any stage of the operation even if the bowel end drops out of the clamp

4. The method of loosening and reapplying the clamps permits more accurate placing of the sutures, with the turning in of the minimum amount of bowel end. If a very thin bladed hemostat had the rigidity of the heavier ones, this step might be avoided.

5. It is important that every stitch must catch up the submucosa if it is to have any holding power.

6. The use of interrupted mattress sutures as the first layer is urged because they prevent the

pursestring effect accompanying the use of a continuous stitch as a first layer.

7. The method described is simple and safe. It is not aseptic, only relatively so. It requires no special instruments or training and by the use of a simple screw clamp the services of an experienced assistant are not essential.

TRANSVERSE UPPER ABDOMINAL INCISIONS

MILLARD S ROSENBLATT M D F A C S and DONALD COLVER M D Portland Oregon

THE transverse upper abdominal incision has many advantages over the longitudinal rectus muscle splitting incision for upper abdominal surgery. These advantages are (1) the blood supply of the abdominal wall is interfered with but little (2) the nerve supply of the abdominal wall is not damaged (3) the wound tends to come together naturally (4) postoperative distention if present puts much less strain upon the wound than when a longitudinal incision is used (5) patients resist deep breathing much less and thus the incidence of postoperative pulmonary atelectasis is lessened (6) it affords better exposure of the upper abdomen with less necessity for the packing away of the small bowel (7) wound disruption is less frequent and more readily repaired when it does occur (8) the danger of postoperative hernia is less (9) patients may be allowed out of bed very early because the sitting or upright position decreases rather than increases the strain on the wound.

The transverse upper abdominal incision also has certain disadvantages (1) it is more time consuming (2) in some cases, if an appendectomy is to be combined with an upper abdominal procedure

From the Division of Surgery University of Oregon Medical School.

it may be difficult or occasionally impossible to accomplish this step through the upper abdominal incision (3) in some cases, in the presence of a narrow subcostal angle the exposure is no better than it is through a longitudinal incision (4) in cases of total gastrectomy while some operators believe that the high left rectus muscle splitting incision gives better exposure, others do not concur in this opinion (5) cutting across the rectus muscle transversely appears to be physiologically unsound and it is because of the fear of possible irreparable damage which may follow that many surgeons prefer not to use this incision.

In order to learn what actually happens to the cut ends of the muscle we made a study of the results in dogs of cutting the rectus muscle transversely and resuturing the fascia without suturing the muscle. After a 2 month interval we reopened the wound and found the muscle densely adherent to itself at the cut ends and also to the overlying and underlying sheath which in effect, gives an additional *inscriptio tendinea* in the muscle.

A study of microscopic sections revealed that the cut ends of the muscle showed the same kind of healing as was found after the use of the muscle fascia suture as done by Koontz, and by Rosenblatt and Cooksey namely a connective tissue union occurred between the two cut ends of the

Fig. 1. Transverse incision of rectus muscle of dog

Fig. 2. Healing 2 months later

Fig. 3.

Fig. 3. Type of union at cut edge of muscle.

Fig. 4.

Fig. 4. Higher power photomicrograph showing connective tissue cells in and around the muscle interlaced with fibrous tissue bridging the muscle gap.

muscle. White fibrous connective tissue cells were always present in the muscle because the muscle bundle was surrounded by a sheaf of white fibrous connective tissue and each muscle fiber was surrounded in a like manner and the entire muscle or group of muscle bundles was also held together by connective tissue cells. These elements from both sides join and make a very firm union due to the fact that the connective tissue elements are anchored like tentacles in and around the muscle fibers and bundles.

A study of the accompanying photomicrographs will demonstrate the presence of the endomysium, perimysium, and myomysium (the connective tissue cells around the muscle) and the hundreds of interlacing strands of connective tissue which in this manner anchor the cut ends of the muscle

together. In general, from our study we are convinced that very firm and satisfactory healing of the cut muscle occurs and that the union thus formed is fascial in character and equivalent to an additional inscriptio tendinea.

In summary, we believe that for many cases the advantages of the transverse upper abdominal incision outweigh its disadvantages. The point of view that cutting across the rectus muscle may lead to difficulties in healing is only psychological, as is evidenced by the type of union obtained in this study.

PRIMARY TUMORS OF THE LIVER

WESLEY N WARVI M.D. Lieutenant M.C. A.U.S. Cincinnati Ohio

THE paucity of recent literature on the subject of primary tumors of the liver and the futility with which such tumors are usually regarded are indicative of the need for pointing out favorable aspects in order that patients who would benefit by surgery will not be denied early adequate treatment.

An outline of primary tumors of the liver excluding tumor like hyperplastic nodules and secondary tumors, will serve as a basis for discussion of diagnosis and treatment

TRUE PRIMARY TUMORS

1. Hepatomas
 - a. Liver cell adenomas
 - b. Liver cell carcinomas with or without cirrhosis
2. Cholangiomas
 - a. Adenomas of intrahepatic bile ducts, solid or cystic
 - b. Carcinomas
3. Cholangiohepatomas of both liver cell and duct elements
4. Tumors primary in the liver but not of specific hepatic elements (vascular fibroses, adrenal rests, etc.)

Adenoma is limited to benign encapsulated tumors of glandular origin and hence excludes all those with blood vessel or regional invasion and those with metastasis. This eliminates such paradoxical terms as malignant adenomas.

Some authors (Benson and Penberthy) would separate the smaller slowly growing benign rests of liver cells from adenomas by calling them hamartomas. However they resemble adenomas in appearance and when large enough to be manifest they behave like adenomas clinically requiring the same kind of treatment and hence there is no practical advantage of attempting a separate classification of hamartomas.

The hyperplastic nodules of multiple foci of regeneration in cirrhotic livers do not meet the criteria of adenomas. They are without true capsules and are only surrounded by condensation of fibrous tissue of the cirrhotic process. They are not autonomous, for their physiologic secretory activity corresponds to that of the rest of the liver and through functioning duct system it is drained with that of the liver as a whole.

Adenomas of liver cells grossly are isolated, encapsulated masses of atypical cells arranged in cords with intervening blood sinusoids,¹ but with

Dr Warvi was killed in an automobile accident after receipt of this manuscript.

From the Department of Surgery, College of Medicine of the University of Cincinnati, and the Cincinnati General Hospital.

no bile ducts or portal trads. The uniform large cells have eosinophilic granular cytoplasm and central nuclei, usually single but at times multiple with minimal proliferative activity and no hyperchromatism. There are no signs of peripheral nor blood vessel invasion and metastasis does not occur from these benign lesions (see Figure 1 a and b of a benign adenoma that was resected)

Carcinoma of liver cells is characterized by increased proliferative activity, resulting in smaller cells with less cytoplasm, loss of granularity, a change from eosinophilic to basophilic staining quality, and nuclear hyperchromatism accompanied by rapid proliferation by amitosis or atypical mitosis. There are no signs of secretion such as gross bile staining or microscopic plugs of inspissated bile nor is there time for calcification of necrotic portions of the tumor as there is in adenomas. Typical lesions of each class are easily recognized but the borderline types cause difficulties in determining the exact pathologic significance and therapeutic requirements.

Cholangiomas are more easily classified into benign or malignant types of either cystic or solid tumors.

Primary tumors from nonspecific elements in the liver such as vascular or stromal tumors, do not differ pathologically from similar tumors in other parts of the body and hence need no special mention.

CLINICAL DIAGNOSIS

Low incidence of primary tumors of the liver is not conducive to frequency of correct diagnosis. At the Cincinnati General Hospital there were 353,971 admissions from 1916 to 1941 inclusive. These admissions were typical of a general hospital and include minor cases as well as readmissions. A total of 73 cases were clinically diagnosed primary carcinomas of the liver on the basis of symptoms and signs as well as x ray and laboratory studies. However only 43 cases had microscopic studies, which showed the clinical diagnosis to be correct in 31 cases and incorrect in 12. This proportion of incorrect diagnoses indicates the clinical error to be 20 of the 73 cases, leaving 53 probable cases or an incidence of 0.015 per cent of total admissions as cases of primary carcinomas of the liver. With a much greater incidence in tropical countries the proportion of correct clinical diagnosis is higher (Tull Strong and Pitts)

TABLE I — FREQUENCY OF SYMPTOMS AND SIGNS IN PRIMARY CARCINOMA OF THE LIVER

Symptoms and signs	27 proved cases of C.G.I.L. Per cent	200 proved cases reported in literature Per cent	34 cases reported by Tull Per cent
Anemia	97	68	38
Weakness and weight loss	94	88	88
Palpable tumor	9	68	68
Jaundice	86	34	34
Pain	7	5	1
Fever	53	34	38
Vomiting	44	1	
Edema of legs	40	60	84
Ascites	37	46	48
Fixed diaphragm	8	30	38
Tender liver	5	7	15

Adenomas of the liver can be diagnosed clinically by symptoms and signs that are of longer duration before the patient finds it necessary to come for treatment and more localized in the right upper quadrant than carcinoma. The presence of an upper abdominal mass and a sensation of fullness or dragging is usually the first manifestation of an adenoma noted by a patient, in contrast to the distinct pain of carcinoma. Local obstructive manifestations affecting the gastrointestinal tract, bile ducts, or portal circulation, causing vague indigestion, vomiting, jaundice, or ascites are more prominent and may eventually cause death without the systemic disturbances of carcinoma and its metastases. Fever is exceptional in adenomas and present only in large ones undergoing necrosis, but is reported present in at least half of carcinomas. Cystadenomas have the signs of a cystic tumor in addition to the manifestations of a mass crowding surrounding structures and hence is more easily differentiated from malignant growths but other lesions must be considered.

Symptoms and signs of primary carcinoma of the liver are given in Table I.

The variations in the percentage of occurrence of manifestations of carcinoma of the liver in the table are indicative of the difference in the behavior of the type of carcinoma predominating in various geographical locations. The symptoms and signs of anemia, palpable tumor, jaundice, pain, and vomiting are associated with tumors of longer duration and of larger size as in our cases, while those of weakness, weight loss, fever, peripheral edema, ascites, and fixed diaphragm are present with rapidly disseminating and invasive tumors such as in Tull's cases. The manifestations in the total 500 cases represent more of an average of symptoms and signs, including those of the highly malignant ones occurring in Asiatic countries as well as those of lower malignancy reported

from Europe and America. Bile duct carcinomas of the liver tend to be more malignant with symptoms and signs of greater severity than those arising from liver cells. In our cases, 9 were of bile duct origin with an average survival of only 14 months from the onset of symptoms to death, in contrast to an average of 8 months' survival in 11 cases of carcinoma of liver cells.

Unusual symptoms and signs have been reported such as those of an acute abdominal accident when spontaneous rupture of a necrotic tumor causes intraperitoneal hemorrhage (Binkley). The pain, fever, and hematemesis from associated esophageal varices adds difficulties to diagnosis of some carcinoma cases. Adhesions about an adenoma may simulate the fixation of carcinoma and can be differentiated only by exploratory laparotomy (Farani).

Laboratory studies as a rule do not aid in differential diagnosis but are essential in determining physiologic disturbances to be corrected before operation. One exception is when a tumor is found associated with jaundice. Then the laboratory findings of acholic stools, absence of urobilinogen and direct van den Bergh differentiate obstructive jaundice suggestive of a large adenoma rather than the hepatic failure of carcinomatous involvement. An anemia must be corrected preoperatively. Prothrombin and bleeding time should be returned to normal. Low results in liver function tests (Bargen and Rankin, Cohen and Helhuis, Moranze, Moranze and Rothman) and the presence of hepatic hypoglycemia would indicate extensive liver damage due to an inoperable tumor.

Biopsy is imperative in diagnosis of liver tumors and it can best be obtained during an exploratory laparotomy, permitting inspection of the tumor for extent of involvement, invasiveness, cellularity, presence of encapsulation or of metastases. No alarming bleeding has occurred if hemostatic sutures are placed in readiness before the excision of an adequate wedge of liver tissue. Peritoneoscopy also offers some opportunity to determine operability in addition to obtaining biopsy for microscopic study (Beling). Aspiration biopsy is reported to give 73.5 per cent correct diagnoses of liver tumors at Memorial Hospital at New York. Punch biopsy has a few advocates.

Diagnostic accuracy in reported cases of resected tumors of the liver is difficult to ascertain, for from a total of 214 cases reported completely enough to tabulate the method of resection, results, and pathologic diagnosis, only 45.1 per cent gave a definite preoperative clinical diagnosis. However, most of those not stating a definite

TABLE II—DIFFERENTIAL DIAGNOSIS OF LIVER TUMORS

Means of manifestation	Benign	Primary malignant	Secondary malignant
Symptoms	Primary of pressure as vague local distress, indigestion or gastric or duodenal displacement	Definite pain with invasion. Systemic symptoms with anorexia, weakness, anorexia. Hemoptysis from esophageal varices or gastric invasion	Symptoms of tumor elsewhere that may be smaller than the liver metastasis. History of removal of possible primary
Signs	Palpable abdominal mass is firm, movable, solitary and rarely tender	Tumor mass is fixed, hard, multiple and often tender	Discovery of tumors elsewhere often with little symptoms
Laboratory	Jaundice, obstructive, if bile duct occluded. Acolic stools. No urobilinogen. Van den Bergh immediate direct. Otherwise physiology undisturbed	Jaundice if hepatic failure with invasion. Stools \pm acholic. Strong urobilinogen. Van den Bergh is indirect. Anemia. Hypoproteinemia	Tests for significant disturbances. If tumor elsewhere as in urinary, gastrointestinal tract, bone marrow etc. Anemia. Hypoproteinemia
X ray	Localized mass in liver displacing other organs as stomach or duodenum	Invasion fixed mass in liver. Duaphragm elevated and often fixed	Search for tumor elsewhere as gastrointestinal tract, etc.
Biopsy	Visualization to show accessibility for resection	Visualization of invasion, multiplicity. Rarely resectable	First of all possible sources including suspicious ovary. Later of liver mass to discover its source

diagnosis carried out therapeutic measures which leaves one to assume a correct preoperative diagnosis was made. Hence the results can be stated thus: Preoperative diagnosis was correct or not stated in 73.2 per cent. preoperative diagnosis was wrong in 26.8 per cent.

At the Cincinnati General Hospital 47 cases of clinically manifest adenomas and carcinomas of liver cells have been studied microscopically. Of these 33, or 70 per cent. had a correct clinical diagnosis before operation or autopsy.

Differential diagnosis is admittedly difficult but often possible when all factors are considered together and for that reason the following diagnostic table is included.

TREATMENT

Adequate noninjurious hemostasis has been the major problem in surgical treatment and the subject of experimental work. That success experimentally is no guarantee against failure when applied clinically was shown as early as 18,9 when Tillman controlled bleeding with ease by simple pressure after ligation of major cut vessels in resected livers of animals. Attempt by Escher to apply this clinically resulted in fatal hemorrhage. The human liver with a pathologic lesion differs by being abnormally friable and highly vascular. Tamponade in various forms, application of hemostatic substances, and reduction of blood supply by tourniquets or clamping about the liver or hepatoduodenal ligament are not entirely successful. Cautery hemostasis proved useful only when it was controllable as by electrocoagulative methods. Hemostatic sutures proved most effective experimentally as well as clinically. Substances used to prevent sutures from cutting into liver tissue have not proved practical. The introduction of blunt needles that push aside blood vessels

rather than penetrate them with consequent bleeding was a real contribution by Kousnetzoff and Pensky.

Indications for surgical removal of primary tumors of the liver depend upon their size, their location with relation to major bile ducts and blood vessels at the hilum of the liver and upon the general condition of the patient including the condition of the rest of the liver. The majority of authors (Scheleff, Tinker, Gray, Cullen, Tuffier, McArthur, Fevre and Dassios) believe resection is indicated in adenomas, cystadenomas, localized solitary carcinomas, and hemangiomas but with the following restrictions: no lymph node metastasis should be demonstrable as in the regional nodes along the vessels at the liver hilum; the tumor should not involve the major blood vessels nor bile ducts at the hilum (Ward) and there should be no marked reduction of hepatic function indicative of extensive involvement of the liver parenchyma (Walton, Nadler and Wolfer). In addition in cases of cystadenomas one must decide whether to marsupialize or resect completely and also one must rule out generalized cystic disease that involves other organs as well. There are surgeons with two extremes of opinions: those who believe surgical intervention is very rarely feasible (Crile, Cole, Alessandri) and those who optimistically resect extensive primary carcinomas with involvement of adjacent organs or even known secondary carcinomas (McArthur, Cattel, Cullen). At the Cincinnati General Hospital an exploratory laparotomy is done when symptoms, signs, x ray and laboratory findings are those of a freely movable tumor of the liver without evidence of metastasis, without marked hepatic insufficiency and without a grave operative risk. Actual resectability can best be determined during the exploratory laparotomy.

mission to the hospital, when she noted a dull pain in the right upper abdomen that extended posteriorly to the inferior angle of the scapula where it was most marked. At the same time she noted a mass in the right upper abdomen that remained unchanged. She felt distended after meals with occasional nausea. There had been no vomiting, jaundice, nor loss of weight. Examination was negative except for the 8 centimeter mass attached to the liver assumed to be of gall-bladder origin.

Operation—performed on November 28, 1934, by Dr. Mount R. Reid. Ether-oxygen anesthesia was used. Through a right rectus incision an 8 centimeter mass was revealed, covered by adherent omentum and attached to the right lobe of the liver by a 5 centimeter base near the fundus of the gall bladder. The cystic duct was divided and the gall bladder freed to point near the tumor. Two rubber-shod clamps were placed across the liver radiating from the hilum proximal to the tumor and (64) interrupted mattress sutures of chromic catgut were placed for hemostasis longitudinally proximal to the clamps. The tumor was then excised with electrocautery and the clamps removed. The cut edges were sutured together with No. chromic catgut suture supported by the longitudinal hemostatic sutures. A cigarette drain was placed down to the stump of the cystic duct and the incision closed.

Postoperatively there was considerable abdominal distention for 3 days, relieved by enemas and pituitrin. The drain was removed on the 4th postoperative day and she was discharged from the hospital on the 10th day in very good condition. She has been seen repeatedly at frequent intervals and has remained in good health over 8½ years, with no signs and symptoms.

Microscopically the tumor was typical adenoma of liver cells completely encapsulated.

CASE 3. C. G. H., No. 6538, A. D. this patient, 38 year old negro, began to have pain in the middle of the back July, 1929, 7 months before admission to this hospital. In October, 1929, he noted a golf ball sized, slightly tender epigastric mass that moved with change of position of the body. He went to several physicians and was given medication without improvement. He was worried and lost 20 pounds in 6 months. An exploratory laparotomy and biopsy of the mass was done March, 1934 at another hospital. He was told that he had an inoperable carcinoma of the liver. He continued to lose weight while seeking treatment elsewhere and entered this hospital November 1934. Our review of the microscopic slide of the biopsy led to diagnosis of an adenoma of liver cells.

Operation was performed November 5, 1934, by Dr. B. N. Carter. It was done through a transverse incision that crossed the right rectus scar of the previous operation and a T-extension was made along the old scar for better exposure. Adhesions had formed between the old scar and tumor to the anterior abdominal wall and the transverse colon and omentum. The structures were freed and the liver tissue compressed by the fingers of the assistant while the tumor was progressively resected with Bowle unit and suture across the line of incision with No. chromic catgut as carried out as the resection progressed. Six cigarette drains were placed down to the charred edge of the liver and the closure of the abdominal wall was re-enforced with silver wire stay sutures. Postoperatively he developed bronchopneumonia, which responded well to sulfathiazole therapy. The thick discharge from the eschar obstructed the drains so that on the 7th day his temperature again rose to 106 degrees. Round rubber drains replaced the cigarette drains and proved to be adequate but he continued to have persistent discharge from the wound for over weeks until the sinus finally closed. Since that time he regained his weight and has been in good health without signs

of recurrence now for over 29 months since the resection of his tumor.

The tumor measured 13 by 9 centimeters and was completely encapsulated. Microscopically it was a typical adenoma of liver cells (Fig. 6).

A review of all reported resections of liver tumors totals 223 cases with complete description of operations as well as microscopic confirmation of diagnoses. Notable reviews of the past include those of Keen, 1892, 1897 and 1899; Anshutz, 1903; Cullen, 1905; Schroeder 1906; Garre, 1907; McDill, 1912; Thole, 1913; Yoernan 1915; Timber, 1935 and Charache, 1939. Since the number of resections performed by any one surgeon are very few, a review of all reported cases offers the only way of adequate comparison of the various methods of resection.

There remain 347 resected cases that could not be included in tabulating and evaluating treatment because the referring authors did not give the source of the report mentioned, became some references were incorrect, some were in unobtainable journals, and a large number did not give adequate information about the case or the diagnosis was questionable. These include 173 resected cases of primary carcinoma of liver cells, 34 resected cases of primary sarcoma of the liver, 26 resected cases of solid adenomas of the liver, 8 resected cases of gall-bladder carcinoma involving the liver, and 6 or more resected cases of cystadenomas of intrahepatic bile duct origin. If all these cases could be accepted, there would be a total of 570 resected cases of liver tumors.

There are 6 common postoperative complications for which the surgeon must be on the alert. (1) Blood loss is no longer as much a danger as it was, for in Keen's review (1899) of 74 cases there were 11 deaths, of which 8 or 73 per cent were due to hemorrhage. Since the beginning of this century in 149 cases resected there were possible manifestations of bleeding with fatality in only 3 cases (Mantle, 1903; Parin 1913; Ramsey 1929) and of these only 1 a hemangioma, had gross hemorrhage. (2) Infected wounds, peritonitis and septicemia are also much less important than in the past. (3) Prevention and chemotherapy have minimized the importance of respiratory complications such as pneumonia and atelectasis. (4) Three forms of metabolic disturbances giving rise to postoperative difficulties are (a) liver shock (Ravdin) or liver deaths (Sutton) which occur earliest, (b) hepatorenal syndrome and (c) general malnutrition largely as hepatic hypoglycemia which occurs late. (5) Postoperative ileus and at times hematemesis follow clamping of hepato-duodenal vessels with engorgement of portal cir-

Fig. 2. Major methods of resection. (1) Elastic ligature and extraperitonealization of the stump (Cousins, 1874). (2) Simple cautery (Parquellin) removal (Echer 1886). (3) Lobectomy with reported less bleeding for physiologic line of cleavage used (Langenbuch, 1888). (4) Hemostatic suture with blunt needle and closure of liver surfaces after resection (Kousnetoff and Penaky). (5) Clamps left on for hemostasis and, a, completely exteriorized (Lapoint, 1897) or b, only the handles exteriorized for removal through a stab wound (Kocher 1903). (6) Excision with tamponade (Anschütz, 1903). (7) Hemostatic sutures placed proximal to clamps and electrocautery excision of tumor distal to clamps. Raw surface closed by interrupted sutures going around the longitudinal hemostatic sutures preventing cutting of sutures through liver tissue. This method was used in Case 2.

culation (6) Persistent sinuses occur with discharge of bile after marsupialization of cystadenomas, with discharge of necrotic slough from an excessively thick eschar of cautery or with discharge of pus from tracts left by drains.

SUMMARY AND CONCLUSIONS

A practical classification of primary tumors of the liver is presented with definition of terms. Emphasis is placed on the pathologic differentiation of true adenomas that are resectable with a good prognosis.

Clinical diagnostic features stress the local manifestations of benign tumors in contrast to the

systemic disturbances of malignant tumors particularly those that are inoperable. Bile duct carcinoma tends to be more rapidly fatal and anaplastic than those of liver cell origin.

Diagnostic error clinically was less than 30 per cent. A table of differential diagnosis between benign tumors, primary carcinoma, and secondary malignant tumors is given.

Treatment of liver tumors must be entirely surgical to be successful. X-ray therapy is not only ineffective but detrimental. Surgical resection should be attempted in all localized liver tumors without evidence of involvement of adjacent organs or too much of the liver itself and should

be deferred until the patient is in best possible condition. After proper preparation the best method of resection appears to be a combination of hemostatic sutures and electrocautery.

Review of literature indicates that 223 resected cases have been fully reported but the probable total number of cases is about 570 when those of limited description are included. It is apparent that the operative mortality is not high but most failures are due to inadequate removal with recurrence.

Postoperative complications are largely those of metabolic disturbances such as early "liver deaths," late "hepatorenal syndrome," or finally malnutrition with loss of resistance to infection. These are preventable.

In conclusion an attitude of futility should not be entertained toward all patients with primary liver tumors.

THE CLINICAL USE OF BORIC ACID

OUR medical journals and daily newspapers announce with grim regularity the tragedy of death from boric acid poisoning in hospitals and clinics all over the country. And it is obvious that the reported cases though seemingly numerous do not constitute the aggregate of victims suffering this tragedy. Evidence that the problem has exceeded the academic stage of discussion is indicated by the fact that the toxicity of this compound was brought up for discussion at the recent National Chemical Exposition and one state legislature already has up for consideration a statute to outlaw its unprescribed use.

The poisonous nature of boric acid was recognized as early as 1883 when Brose reported a death following its use as a dusting powder on a chronic leg ulcer. Subsequent reports have demonstrated its toxicity when absorbed from the gastrointestinal tract or when administered parenterally and poison-

ing has been described in infants who have suckled from nipples cleansed with saturated boric acid solution. There have been reported numerous deaths due to the absorption of the drug from cavities such as the pleura, that have been irrigated with solutions of boric acid in the treatment of infections. Recent investigations by the Naval Medical Research Institute have demonstrated that boric acid whether applied in the form of a saturated solution or as an ointment is absorbed from extensive wounds or burns and is a cumulative poison.

Investigation into the mode of administration in fatal cases discloses that in some instances poisoning occurs when the physician who prescribes it does not know of the harmful nature of the drug while in other instances the toxic substance is unintentionally substituted for an innocuous solution. Typical accidents that have occurred repeatedly are the intravenous administration of boric acid solution in the place of glucose or saline solution which had been prescribed and the preparation of infant feeding formulae with boric solution instead of sterile water. The frequency of such unwitting and accidental poisoning suggests that the universal employment of boric acid today constitutes one of those habits acquired by inheritance—and never critically evaluated.

The medical profession has used boric acid since Joseph Lister in 1875 in his communication entitled *On Recent Improvements in the Details of Antiseptic Surgery* first described its use in clinical medicine. Lord Lister had employed it himself first in the treatment of an onychia on his little finger. He observed that a dressing saturated with

boric acid was more soothing to his finger than one with carbolic solution and that the infection subsided promptly after its application. He concluded: Here then I had at once sufficient evidence that the new antiseptic, when employed in the form of a watery solution, was both highly efficient and much less irritating than carbolic acid. The general acceptance of this innocuous odorless and practically tasteless substance was no doubt enhanced when its mildness was compared to the robust character of the antiseptics that were the order of the day. Boric acid was soon

widely used for the dressing of wounds and for the irrigation of inflamed cavities.

The widespread use of boric acid solution today probably derives chiefly from the inertia of established custom and its clinical survival no doubt results more from its property of blandness than from any of its other attributes, for it is not a satisfactory antiseptic. On the basis of our present knowledge of its toxic properties boric acid should be regarded by the medical profession as a poison and should be handled as such.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE third edition of *Interns Handbook*¹ is a small volume planned to fit the coat pocket of its owner yet supposed to contain a complete summary of medical and surgical therapeutics. Its opening pages deal briefly with instructions for the interne concerning his duties and responsibilities in hospital life. This is followed by a section on medical laboratory techniques. The third and fourth parts are given over to medical and surgical procedures, while the last section concerns itself with a description of numerous drugs and biologicals.

In general the aim at completeness in scope has resulted in an unbalanced spread of details. An attempt has been made to cover all disease entities with no heightened emphasis upon situations which commonly arise. The chief example of its sparseness of detail is the section on surgery where only general outlines are given, while the rarest of medical situations appear to be very well anticipated. While brevity is the byword throughout, the sections on laboratory techniques and pharmacology have used space which otherwise could have been devoted to clinical procedures whose details often are hidden in the literature yet are well known to more experienced practicing physicians. There is no doubt but that the text has merit because it is such a compilation but one feels that it will be more satisfactory to a senior medical student just starting his hospital experience than to an interne who is about to accept a greater degree of responsibility.

This text cannot supplant the average hospital procedure book, but in the absence of the latter it will be an aid to the unguided interne who feels the need of readily available pocket information.

WALTER W. CARROLL.

IN the fourth edition of the former *Manipulative Surgery*² many additions and alterations have been made and some sections have been largely rewritten. A number of new illustrations of manipulative technique have been added.

Misapprehension frequently exists among the profession as to what manipulative treatment means and what it can achieve. There is also a tendency to emphasize unduly the dangers of manipulation. This book shows exactly what treatment by manipulation means and that intelligent discrimination is as necessary in this as in any other branch of surgery.

INTERNS HANDBOOK. By members of the Faculty of the College of Medicine, Syracuse University. Under the direction of M. D. Dealey, A.B. M.D. and Maynard E. Holmes, M.D. F.A.C.P. 3d ed. Philadelphia, London, and Montreal: J. P. Lippincott Co. 944.

TREATMENT BY MANIPULATION IN ORTHEDIC AND CONJUNCTIVE PRACTICE. By A. G. Tibbitts Fisher, M.C., M.B. Ch.B. F.R.C.S. (Eng.). New York: Paul B. Hoeber Inc. 944.

This subject is not sufficiently emphasized in the curricula of our medical schools. Cures by manipulation are so many and so well authenticated that the subject demands the fullest investigation. The subject should be taught by lectures upon the underlying pathology and by actual practical demonstration in our medical schools and hospitals. Interest and enthusiasms must be aroused. Research must be conducted into underlying physiological and pathological principles. Careful records must be kept. These procedures should be easy for every out-patient department contains cases which urgently need manipulation.

This book points the way to accomplish good results by manipulation. Surgeons should read this book to see what the author, an orthopedic surgeon, believes treatment by manipulation will accomplish.

JOHN S. COULTER.

SOME investigators have recognized a relationship between immunochemistry and enzyme chemistry yet physiological chemists in general have paid little attention to immunity and conversely immunologists have had small interest in the chemistry of enzyme action. *Immuno-Catalysis*³ by M. G. Sevag is an able elucidation of the author's theory of immunocatalysis. He demonstrates by an extensive and wise use of the literature the many parallelisms between protein antigen and enzymes and between antibodies and antisymes and by integration that antigens show properties which satisfy the well known criteria of catalytic agents and that specific antibodies formed as final reaction products in response to antigenic stimuli fulfill the function of specific inhibitors of enzymes. The book will especially interest immunologists and biochemists and act as a challenging incentive to further research. It is an excellent review of the literature with an exceptional bibliography.

A. A. DAY

BECAUSE of the outstanding qualities of the authors and widespread acceptance of their leadership in this field, it may seem unnecessary to review the book *Essentials of Oral Surgery* by Blair Ivy and Brown⁴ who, in long association, have been authoritative teachers of surgery and diseases of the oral cavity.

The arrangement of the material in the book conforms to that of Blair's original text *Surgery and*

¹INTERNS-CA ALBERT. By M. G. Sevag, Ph.D. Springfield, Illinois, and Baltimore: Maryland: Charles C. Thomas. 945.

²ESSENTIALS OF ORAL SURGERY. By Wilbur Fyfe Blair, A.M. M.D. F.A.C.S. and Robert Henry Ivy, M.D. D.D.S. F.A.C.S. with the collaboration of James Barrett Brown, M.D. F.A.C.S. 3d ed. St. Louis: The C. V. Mosby Co. 944.

Diseases of the Mouth and Jaw published in 1912 and much of this material has been retained. The new book, with the collaboration of the present authors, has been brought progressively up to date to the present third edition.

Primarily intended as a text and guide in surgery for dental students the book maintains that objective and further provides a valuable source of information for medical students and practitioners on a subject rather neglected in medical education. The scope of the book is tremendous and most revealing to one not particularly familiar with the diseases and affections to be found in the oral cavity.

Particular importance is attached to the need for recognition of surgical conditions and, while the opening chapter deals exclusively with examination, anatomical considerations, and study leading to diagnosis, this emphasis is stressed throughout the book. This sound approach to the subject is founded on the unusual combination of abilities of these individual authors as teachers, clinicians, and resourceful surgeons. In this book the dentist will find the solution to his most disturbing problems—those concerned with acute and chronic infections and inflammatory conditions arising about the teeth,

fractures of the jaws, dislocation of the jaw and the loss of teeth or roots in the antrum.

The chapter written by Dr. Kazanlian on the surgical preparation of the mouth for artificial dentures will be particularly appreciated by the dentist who is anxious to improve the efficiency of his prosthetic efforts.

With the exception of the chapter on fractures of the jaws, that dealing with tumors is given most space (68 pages). This is one of the most important chapters in the book and the emphasis laid on pre-cancerous lesions and cancer of the mouth and jaw bones is desirable and commendable.

The rôle of the dentist in the control of cancer is definite, and the plea is made for fundamental knowledge of oral pathology and a routine and complete survey of the whole mouth.

New material has been included to bring the sections on shock, hemorrhage, burns and wounds up-to-date. Developments in the treatment of fractures are described and illustrated.

This book of 624 pages, with 467 uniformly good illustrations, is a desirable textbook for dental students and medical students, and deserves a place in the library of every surgeon and dentist.

FREDERICK W. MERRITT.

AMERICAN COLLEGE OF SURGEONS

GRADUATE TRAINING IN SURGERY AND THE SURGICAL SPECIALTIES

CHARLES R. REYNOLDS M.D. Major General U.S. Army (Retired) Chicago Illinois

THE Surgeon General of the United States Army has announced that of the wounded who live to reach Army hospitals, more than 90 per cent are being saved. This is not entirely due to chemotherapy and the use of penicillin and blood and blood substitutes but to a large extent is the result of sound surgical principles applied to trauma. The surgical profession may well be proud of that accomplishment. Looking back over the road it has come, the profession knows that the surgical proficiency of today is the fruit of the decisive planning of yesterday through which the more or less haphazard apprenticeship system of training has been rapidly supplanted by scientifically set up well rounded programs of graduate training in surgery.

Right now when scientific surgery is being put to its supreme test is the time for surgeons to resolve that the unavoidable disruption of surgical education by the war must be compensated for at the earliest possible moment. The temporary setback must be repaired by postwar plans so complete and progressive that they will take up the wartime lag and reinstate surgery on its former march.

Dr Dallas B. Phemister chairman of the Committee on Graduate Training in Surgery of the American College of Surgeons said in an article in the February 15, 1942 issue of SURGERY GYNECOLOGY AND OBSTETRICS: "The needs of our military forces must be met and under the present world conditions some of our most desirable and ambitious plans may have to be changed. The prediction has come true. We have had to curtail training in surgery at a time when we urgently need more and better trained surgeons. A decreasing number of trainees have been permitted to carry their educational programs through to completion. As the months pass and the war lengthens the situation becomes increasingly grave."

Consultant in Graduate Training in Surgery American College of Surgeons.

EFFECTS OF PRESENT WAR ON MEDICAL EDUCATION

Under the Army specialized training program and the Navy V-12 program medical education on the undergraduate level has up to the present time been maintained on a reasonably normal basis considering the disruption of facilities and hospital staffs. The accelerated program has made possible the graduation of 5,500 doctors every 9 months or at the rate of 7,000 every 12 months. Of course, the majority of the war time graduates enter military service after a 9 months' internship. The induction of premedical students will result in a decrease in graduates, and by 1948 and 1949 in shortage of physicians, calculated on a prewar basis.

Under the 9-9-9 plan hospitals may retain for a 9 months assistant residency one-third of the men who complete the 9 months general internship and may keep for a further 9 month period one-half of those who complete an assistant residency. As Dr Frank Lahey chairman of the Directing Board of the Procurement and Assignment Service has said, "The 9-9-9 program is working fine but no one likes it. Inadequate training is given the young men and they are not qualified under it to go out and practice medicine of a standard that the medical profession has set. It is a makeshift and compromise system which is one of the sacrifices that it has been necessary to make to win the war. Its faults make it the more urgent that plans be set up for further training of these men when the war is over. The abbreviated or hurried curricula in medical schools, the depletion of school facilities and hospital staffs, and the abbreviated internships and curtailment of training at the residency level all conspire to set back medical education in this country not only during the war but for several years afterward."

Great credit should be given to medical schools and teaching hospitals which have carried a heavy load of undergraduate and graduate education with depleted staffs.

PROFESSIONAL EXPERIENCE WHILE IN MILITARY SERVICE

As in all recent wars great advances in medical science are being made in this one. These have become evident in preventive medicine, treatment of tropical diseases, in chemotherapy and the use of penicillin in medical and surgical conditions, the use of blood and blood substitutes, in traumatic surgery and the control of wound infections and the treatment of burns and in the broad field let us call it reconstruction surgery wherein are to be included orthopedic, vascular, neurological, and plastic surgery and physical medicine.

By reason of concentration in large hospitals the casualties of war are conveniently arranged for medical and surgical practice and research on a very broad scale. Where in peacetime are to be found hospitals of 5,000 to 10,000 beds set aside for the care of special diseases and injuries? It is safe to say that there are several Army hospitals which are now caring for more neurosurgical cases than all the civilian hospitals in the country combined. The same may be true, to a less extent, as to amputation, fracture, vascular orthopedic, and other cases for physical rehabilitation.

Unfortunately the great or overall advantages accruing to medicine as a result of this war are not participated in by a large proportion of the younger medical officers. When many of these men balance experience gained in the war against the loss of several years of training and practice, particularly if their specialty is surgery they will find themselves several years behind their programs of graduate training.

Senior medical officers naturally occupy the higher professional positions where they are privileged to preserve or advance their professional status. The junior officers, with exceptions, are assigned to troop duty or small medical units. This being the toughest war in history, the demand for the young and vigorous and the tables of organization which determine assignments naturally place a preponderance of young medical men with the combat forces. The recent medical graduates fall into this group. Those who planned or started a surgical career have certainly had their graduate training "impeded, delayed, interrupted or interfered with," as expressed in the subsection on education of the "G. I. Bill."

The scope of wartime medical and surgical practice in the Army except in some of the general and large area hospitals, is lacking in several important features which are necessary in a well rounded program of graduate training in surgery and the surgical specialties.

This is not to imply that all young medical graduates who enter the Army and Navy say goodbye to their graduate training plans for the duration. Those who are fortunate enough to serve in general or large area hospitals find themselves associated with specialists of the highest caliber drawn from medical schools, teaching hospitals and clinics. Clinical material, though not diversified to cover the entire field of surgical training is available. It is known that most of these hospitals are making a point to carry on comprehensive training programs for younger medical officers and otherwise to meet the "essentials" as laid down by the American Medical Association and the "standards" of the American College of Surgeons.

However surgery at the front is limited quite largely to emergency surgery in which many junior officers see only the early treatment and, except when serving with auxiliary surgical operating units, do not take part in the definitive operative procedures and the postoperative care and rehabilitation of war casualties.

The age of the patients is young, mostly males from 18 to 38, with the exception of officers. Consequently the medical officer gains relatively little experience with the conditions prevalent in middle and old age groups, such as the degenerative or chronic diseases—conditions becoming year by year more prevalent and of increasing importance to surgeons. There is also scarcity of experience in care of women and children, many getting no experience in obstetrics, gynecology and surgical conditions of children and adolescents. Their experience is extremely limited too regarding the chief causes of death—heart disease, cancer and apoplexy.

Another factor detracting from the educational value of medical experience in this war is the likelihood of prolonged absence from laboratory and research projects and from experience with the newer medical and surgical procedures in hospital practice.

It will be from this group of 18,000 or more younger medical officers, that requests for graduate training in surgery of a comprehensive type will come. Among its other objectives, the American College of Surgeons recognizes an obligation to develop programs and facilities that will make it possible for future Fellows to meet the requirements for fellowship especially in relation to graduate training in general surgery and the surgical specialties. Professional experience gained in military service will be evaluated and credit given by the College and the boards of medical specialties.

PROGRESS OF GRADUATE TRAINING IN SURGERY

At this point it might be well to trace the origin and development of the system of graduate training that is recognized today to constitute adequate preparation for surgery. Nearly 30 years ago at a meeting of the Southern Surgical Association, Dr Thomas S Cullen of Baltimore credited the American College of Surgeons with beginning remedial measures to control unwarranted operating by inexperienced men. That the most progressive minds in the profession were already thinking in terms of the extended training which all of us consider essential now is shown by the further remarks of Dr Cullen as follows:

"The medical student who after graduation decides to make surgery his life work should not take up his chosen specialty at once but should spend at least one year in a strictly medical service. A broad foundation in general medicine is absolutely essential. The following year can be most profitably spent in the pathological laboratory in making and cultivating the bacterial flora associated with them. After this he should become a surgical interne under a competent surgeon. His time will now be occupied in taking histories, assisting at operations, and in the after care of patients. He will also have ample opportunity for studying all tissues coming from the operating room. He thus has a complete picture of the patient's condition from the time of admission until his discharge, and from the laboratory findings has a clear idea as to the ultimate prognosis of the case. After he has assisted from one to two years, he is allowed to perform the simpler operations, and by the end of the second or third year he is competent to handle the more difficult cases. After a year or two as resident surgeon he is amply fitted to start out as a full fledged surgeon, with the definite knowledge on the part of the hospital that he will be a credit to the school and to the institution from which he has come."

Dr Cullen went on to say that a lack of knowledge of pathology "is the weakest point in American surgery today" and we agree with his conviction that to practice surgery without an adequate knowledge of surgical pathology is like building upon the sand.

Again and again through the years we find individual surgeons voicing the hope that the training of surgeons be placed on a scientific plane. The American College of Surgeons began to give the subject continuous consideration from 1930 on. In 1933 Dr William D Haggard told members of a Hospital Standardization Conference sponsored by the College that the most satisfactory preparation for a surgical career was a residency in surgery after a general hospital service in a university or other hospital for 2 to 5 years, combined with some teaching. In 1935, Dr Edward W Archibald in his presidential address to the American Surgical Association said in part:

"There has arisen in considerable numbers a certain type of surgeon which we all recognize and deplore. He is the natural product of those discoveries and inventions—an

esthesia, asepsis, fine tools, and well equipped small hospitals—which have rendered the practice of surgery in its purely mechanical aspects, relatively safe. He is progressive, venturesome, and self-confident, and such qualities are perhaps those which have placed the best of American surgery in its present proud position. But in the particular type to which I refer, venturesomeness becomes foolhardiness, and self-confidence is uncontrolled by knowledge. To such a man the sum of acquired knowledge is comprised in the popular theories of the year just past. Theory is counted as fact, the hypothesis as a thing proved. A decision to operate is based upon a medical catchword or a rule of thumb. Fingers replace brains, and handicraft outruns science. The result is that such a surgeon is apt to undertake operations which may be technically possible but which are scientifically unjustified."

Important developments with respect to stimulation of interest in proper training were organization of the American College of Surgeons in 1913 and formation of the specialty boards. The first specialty board the American Board of Ophthalmology was incorporated on May 3 1917 to examine candidates and to certify those who passed the examination. The American College of Surgeons provided office space and secretarial aid for the first two years of this Board's existence. Ophthalmology as a specialty in America began in 1855 when Elkanah Williams, of Cincinnati introduced the ophthalmoscope to this country and became the first American physician to limit his practice exclusively to ophthalmology and otology. Independent departments of ophthalmology and otology were established beginning with Cincinnati in 1860 Bellevue in 1868, Rush in 1869 Northwestern in 1870 Harvard in 1871 and Pennsylvania in 1872. Despite this academic recognition ophthalmology was treated like a step-child, S Weir Mitchell declaring in 1891 that he could remember the day in Philadelphia when older physicians refused to recognize socially a man who devoted himself to the eye alone.

In 1869 the Committee on Specialties of the American Medical Association resolved that this Association recognizes specialties as proper and legitimate fields of practice" but admitted that there were objections to specialties because they operate unfairly against the general practitioner in implying that he is incompetent to properly treat certain classes of diseases and narrowing his field of practice.

At any rate, specialization grew. In 1924 the board of otolaryngology was established in 1930 the board of obstetrics and gynecology in 1932 the board of dermatology and syphilology and in 1933 the board of pediatrics. Three boards were established in 1934 orthopedic surgery psychiatry and neurology and radiology. The board of urology was established in 1935 the boards of pathology and of internal medicine in

1936 the boards of surgery and of plastic surgery in 1937 the board of anesthesiology in 1938 and the board of neurological surgery in 1940

THE AMERICAN COLLEGE OF SURGEONS PROGRAM

The American College of Surgeons appointed a committee in 1928 to study what the requirements should be for training in surgery. They contributed a great many ideas. Finally in 1935 a committee under the chairmanship of Dr Samuel Harvey New Haven, professor of surgery Yale University Medical School, brought in a report supplemented by related reports by the associate directors of the College, Dr Bowman C. Crowell and Dr Malcolm T. MacEachern. Out of this study came the present plan for the promotion of training in surgery. This was followed by surveys in 1937 and 1938 for the establishment of a Minimum Standard, now used in the promotion of the work of graduate training in surgery and reproduced in this article.

A list of hospitals of the United States and Canada approved for graduate training in surgery was published first in January 1939. The "Approval Number" of the *Bulletin* of the College published in October 1940 contained a list of 300 hospitals which met the Minimum Standard for graduate training in surgery and also a directory of the approved plans including detailed descriptions of the provisions for basic science study, supervision and the gaining of practical experience. The directory was the first presentation of selected graduate training programs that had ever been made available to the graduate in medicine as a guide in his plans for qualifying himself to practice surgery. It makes possible careful selection of the institution which offers the program best suited to the individual's needs and offers ready opportunity for comparison of programs of different institutions. The new edition of the directory which will shortly be issued will bring the most up-to-date information regarding the approved programs to medical officers looking forward to demobilization and resumption of training. Other information of this nature will be imparted by the College upon inquiry received direct or through the information bureau of the American Medical Association.

One of the chief aims of the College in this program is to increase the opportunities for acceptable training in the moderately sized communities as well as the large medical centers, which will result in the distribution of surgical skill better suited to population requirements.

Preparation for the practice of surgery or a surgical specialty is so long and complicated a

process that careful planning is essential. It has been the experience of the American College of Surgeons in studying the qualifications of applicants for fellowship that a large proportion either fail to make suitable plans for training, or even from the course after they have embarked upon what would have been a suitable program. Advice is constantly being given concerning reconstruction of plans that have not provided the proper background. Considerable time must be spent with each individual advising and helping him with his problems, and the outlook is that the need for this service will be vastly increased when demobilization begins. The problems of evaluating experience while in military service will be added to those of appraising the training received prior to entering the service.

It is expected that physicians who will desire training in surgery after the war will be of 5 general types. These are listed as follows in the "War Issue" of the *Bulletin* of the American College of Surgeons, June 1944¹

1. Physicians who planned to specialize in surgery but who were commissioned immediately following their internships.
2. Physicians whose residencies in surgery were interrupted by military service.
3. Physicians who, under the g-o-g plan, were deferred, receiving one or two g-month periods of graduate training, and who will therefore require additional months of training to complete 3 full years following a 1 month's internship.
4. Physicians who in military service have received some training in surgery which, supplemented by further training, would be recognized as acceptable preparation for the practice of surgery.
5. Physicians with acceptable qualifications who had been in general practice prior to military service and who have gained a desire to specialize in surgery.

The American College of Surgeons, through its Department of Graduate Training in Surgery is pledged to give every possible assistance to the returning medical officer who desires to complete his training so that he may achieve his aim of meeting the criteria of fitness in the specialty of his choice.

Sixty thousand of the approximately 135,000 physicians engaged in active practice in the United States are serving with the armed forces. At present, some 18,000 of these are recent medical graduates whose training has been interrupted. An analysis of about 21,000 returns from the questionnaires sent to 60,000 medical officers by the American Medical Association indicates that four fifths want some kind of postwar training. Three-fifths indicate desire for long courses and one-fifth prefer short courses (less than 6

¹MacEachern, Malcolm T. Bull. Am. Coll. Surg. 1944, 49, 101.

MINIMUM STANDARD FOR GRADUATE TRAINING IN SURGERY

1 DURATION AND OBJECTIVE Graduate training in general surgery and the surgical specialties shall be of sufficient duration and educational content to enable the young surgeon upon completion of such training to begin the practice of surgery in a scientific manner. An acceptable program requires a minimum of two and preferably three or more years.¹

2 ORGANIZATION AND SUPERVISION (a) The medical staff shall be organized with heads of departments and a representative committee responsible for the organization of the graduate training program and for the personal supervision and direction of the work of the resident staff. (b) The hospital shall keep such records of the activities of the resident staff as may be necessary to assure an equitable distribution of work, and together with some form of examination provide a basis upon which the plan of graduate training may be evaluated.

3 BASIC MEDICAL SCIENCES (a) The hospital shall maintain a clinical laboratory an x ray department and other adjunct diagnostic and therapeutic facilities essential for diagnosis and treatment. Facilities for other basic science study, research and investigative work are desirable. (b) All services shall be under the continuous supervision of accredited heads of departments and have qualified technical assistants. (c) The resident staff shall be

required to observe and participate in autopsies to devote adequate time to the study of gross and microscopic pathology, to acquire a degree of practical knowledge of clinical roentgenology and radiology to pursue anatomical studies by dissections on the cadaver and animals to participate in clinical or experimental research or to devote definite time to other study of the basic medical sciences.

If not available within the hospital, provision for adequate collateral study of the basic medical sciences shall be provided through affiliation with another hospital or educational institution.

4 CLINICAL MATERIAL (a) The hospital shall have an active surgical service and an organized outpatient department with systematic follow-up clinics. (b) The number of patients shall be adequate to give the resident staff opportunity for training and experience in the diagnosis, treatment, and study of end results of a variety of surgical conditions. (c) Operative experience under supervision sufficient to obtain a degree of technical efficiency shall be provided for the resident staff.

5 ORGANIZED STUDY (a) The hospital shall provide a medical library containing a wide range of standard textbooks, current medical journals and periodicals with a librarian in charge. (b) A definite program of reading of scientific literature under guidance of the medical staff shall be required, and the resident staff shall take an active part in general staff conferences, departmental conferences, clinicopathological conferences and be responsible for some teaching activity.

¹Since the Minimum Standard was adopted, the Committee on Graduate Training in Surgery has agreed that the duration of an acceptable program should be three or more years following internship; this change in Clause I awaits the official consideration of the Board of Regents.

months) Applying these factors to the total of 60,000 it will appear that 48,000 medical officers now in service will look for postwar training.

The following are extracts from the report of the replies sent to medical officers in the armed services as compiled by Lieutenant Colonel Harold C. Lueth, M.C. Surgeon General's Office Liaison Officer American Medical Association.¹

"Requests for short courses included all specialties. The largest number of requests were for the following specialties in order of frequency: internal medicine, surgery, general review, obstetrics and gynecology, pediatrics, otolaryngology and ophthalmology.

The 10 most popular special fields of training by means of long courses, in order of frequency of request, were surgery, internal medicine, obstetrics and gynecology, general review, psychiatry and neurology, pediatrics, orthopedic surgery, ophthalmology, radiology and otolaryngology.

"Nearly two-thirds of the group, 73,333 or 63 per cent, expressed a desire to become certified specialists. There were 3,324 medical officers, nearly 16 per cent of the entire group, already certified by the American specialty boards. The remainder either did not care to be certified or did not mention their desires.

¹Am. M. Ass. 945, 7-63

"Nearly 40 per cent, 8,734 medical officers, came from private practice to the military services. Twenty-two per cent, 4,640, came directly from internships—nearly 10 per cent, 3,191 came directly from residencies, and the remainder came from various types of practice. About 15 per cent failed to answer the question concerning their previous type of medical practice.

"A comparison of the results of a pilot questionnaire and the present questionnaire was made. Long courses were requested by about one-fifth more in the final questionnaire than in the pilot questionnaire. Only two-thirds as many men requested short courses in the final questionnaire as in the pilot. The difference was attributed to a change of viewpoint of medical officers during the interval between the circulation of the questionnaires rather than to an error in sampling."

Very significant in this report is the number of medical officers who entered military service directly from internships—22 per cent—and 10 per cent additional directly from residencies.

The importance of training for demobilized physicians is well expressed in the interim report to the Senate Committee on Education and Labor from the Subcommittee on Wartime Health and Education dated January 2, 1945, quotation from which follows:

the accelerated undergraduate courses, and the shortened internships and residencies, will make it necessary to provide further supervised training for many recent graduates unless the future quality of medical and dental practice is to be jeopardized. Most of the young graduates are well aware of this. Neither the need nor the demand for postwar advanced medical training can be met with the graduate teaching facilities and staffs now available in medical schools. Expansion of such facilities through increased provision of teaching hospitals and medical centers, as part of the program hereinafter described and recommended, will therefore be required.

As new medical graduates go into service after the abbreviated 9 months internship and as current graduates, postwar, swell the numbers of those wanting and needing surgical training it becomes obvious that hospitals will be swamped with demands for training appointments when demobilization begins. It is fair to assume that at least 15,000 medical officers now in service will require some kind of surgical training at least 10,000 of whom will require extended training in surgery and the surgical specialties. There will be at least double the number of applicants for training than could be accommodated in the 235 hospitals which after survey and careful study of the findings have been approved by the American College of Surgeons for graduate training in surgery and the surgical specialties. Those hospitals are organized at present to train about 1,234 surgeons, with a possible expansion in the crisis to 1,900. Among these are the hospitals connected with medical schools which have been carrying the major load in graduate education and have been getting excellent results. They cannot accept much more responsibility. Their contribution must be supplemented by the educational efforts of non-university connected hospitals. Therefore about 250 additional hospitals must be assisted in creating a total of approximately 3,000 residencies in surgery to be ready to meet the expected requirements of those now with the armed forces. This places the problem squarely before us of surveying a total of at least 500 hospitals. The rate of release from military service, though not yet known is quite certain to result in a substantial demand soon after the cessation of hostilities in either major theater.

To further the program the Department of Graduate Training in Surgery has been expanded. On October 1, 1944, Dr. George H. Müller, formerly dean of medicine, American University of Beirut, Lebanon, Syria, joined the staff as director of educational activities. At the same time, the writer was appointed consultant in graduate training in surgery. Dr. Paul S. Ferguson who has been on the College staff for a number of years and has been in charge of surveys for gradu-

ate training in surgery was appointed director of surveys. The field staff for survey work will be enlarged to include at least 4 competent assistants. In addition the field men making the regular Hospital Standardization surveys under the direction of Dr. E. W. Williamson, assistant director of the College, assist with the work in graduate training in surgery. The associate directors, Dr. Malcolm T. MacEachern and Dr. Bowman C. Crowell, are very active in the work.

In undertaking this program the College has had rich experience over a period of 27 years in its Hospital Standardization program and has obtained valuable data upon which to base its program for graduate training in surgery. It has on file about 60,000 reports of hospital surveys.

Although general principles governing educational content of the training plans have been laid down in the Minimum Standard which accompanies this article, no set pattern can be developed because of the wide variations between the institutions which can furnish acceptable training. After certain fundamental requirements are met, there is room for considerable latitude in the details of operation. The essentials are concerned with duration, which must be not less than 3 years following internship, organization and supervision, which implies a well organized medical staff including exclusive specialists in their respective fields who possess teaching ability and who are given definite teaching responsibilities including supervisory duties and the selection and examination of graduate students, ample provision of facilities for and supervision of basic science study, an active surgical service, an organized outpatient department, and sufficient patients to provide ample clinical material and operative experience, under supervision, for the resident staff and provisions for organized study through a medical library and a definite program of reading and scientific reviews, in addition to participation in general staff, departmental and clinicopathological conferences, and opportunities for some teaching activity on the part of residents.

Within this framework there is room for individualization according to the type of institution, whether it be the large hospital directly connected with a medical school, the small hospital which arranges affiliations with other hospitals for broader clinical experience and with a medical school for basic science study, or the clinic which adds to its well set up apprenticeship type of training closely supervised by thoroughly qualified surgeons the benefit of facilities for study of the basic medical sciences and research.

The greatest obstacle to most hospitals in setting up graduate training in surgery programs is an arrangement for study of the basic medical sciences. It is difficult to lay down a definite program for graduate training in the basic sciences as there still exists a difference of opinion as to just what constitute the basic sciences in relation to surgical training or at least to what extent and when these should enter into the graduate program. Authorities, however seem to agree that they include anatomy physiology biochemistry pathology, bacteriology and roentgenology and that at the graduate level they should be taught by the applicatory system so far as possible. Some believe that they should be taught over a period up to 12 months at the beginning of the training program or in a subsequent year whereas others believe this training can be obtained throughout the several years of residency in hospitals well organized for educational purposes. The latter lean especially to the idea of the resident obtaining this training through special research projects so far as practicable. Perhaps the consensus is that so far as pathology and roentgenology are concerned, hospitals which have competent pathologists and radiologists on their staffs may be able to arrange teaching programs right in the hospital throughout the residency. The same is true of biochemistry and bacteriology which can usually be taught by practical experience in the laboratories. For the teaching of anatomy and physiology on the other hand, definite medical school affiliations are most desirable although there will be cases of hospitals which can furnish excellent resources for study even in these subjects. In general, however hospitals cannot provide opportunities for cadaver dissection due either to lack of facilities or to legal restrictions.

In approving hospitals for graduate training full consideration is given to all of the factors involved in a given situation with proper credit for resourcefulness in devising ways of giving the students adequate training—there is no set pattern that will govern all cases, and no intention to handicap certain hospitals by adhering to a rigid, specific plan that they cannot possibly meet.

Studies now being made by Dr. George H. Miller of the College staff by personal visits to selected medical centers in the United States and Canada to study existing plans and further possibilities for co-ordination of graduate training between hospitals and medical schools will throw much light on the means of solving the problem of the basic medical sciences an up-to-date knowledge of which will be especially valuable to those returning from military service. Under all

circumstances it is essential for a man preparing to become a competent surgeon to know the fundamental sciences. To ignore the applied sciences in the scheme of training would lower the standards of surgical practice.

The picture before us is the medical veteran returning home after making a substantial and costly contribution to his country's security. He is asking and will expect, to re-establish himself in the study or practice of surgery in the most approved scientific way. From the standpoint of patriotism alone that obligation on our part is a compelling one. If this situation is not met substantially as the College proposes to meet it, the result will be distressing disillusionment, occasioned by many young medical men having to go into practice without completing their plans for special training and a serious setback to the standards of surgical practice so substantially advanced in this hemisphere in recent years.

Another consideration is that medical education has been practically suspended in many of the countries of Europe and Asia. For years to come the United States and Canada will be looked upon as centers for postgraduate medical education to meet the requirements of students in war torn countries as well as those from South and Central America who even before the war had begun to seek training opportunities in North America.

THE G. I. BILL

The financial problems of the demobilized physician who wishes to resume his training will be somewhat simplified by the Service Men's Readjustment Act, popularly known as the G. I. Bill which was approved on June 22, 1944. Under this Act a veteran while enrolled in and pursuing a course of education or training in an educational institution which term includes teaching hospitals may be paid a maintenance allowance of \$50 per month if without a dependent, or \$75 per month if he have a dependent or dependents. Medical schools and hospitals may also receive up to \$500 a year to cover cost of tuition laboratory fees books supplies and equipment exclusive of any charge for maintenance for each student who is accepted for training under the G. I. Bill. To be eligible for educational benefits the discharged veteran must have been in active service not less than 6 months, or shall have been discharged or released from active service by reason of an actual service incurred injury or disability.

GRADUATE TRAINING IN GOVERNMENT HOSPITALS

The College has surveyed 31 United States Naval Hospitals 9 United States Public Health

Service hospitals, and 20 Veterans Administration hospitals, to determine their qualifications for graduate training in surgery. It seems impracticable to establish comprehensive programs of training in Army hospitals under existing military conditions, but such training may be considered as a postwar program. However short courses of training "on the job" for volunteers are now being carried on in selected hospitals, chiefly for the benefit of medical officers who have been on administrative duty or in combat areas where opportunity for professional service has been lacking. Plans are now under way to establish graduate training programs substantially as formulated by the American College of Surgeons extending over a period of 4 years, less credit for worthwhile experience, in a number of hospitals of the Navy, the United States Public Health Service and the Veterans Administration. What has been said before regarding the clinical material in service hospitals available for surgical training should be borne in mind in estimating this feature of the program of the College.

It is likely that long or comprehensive programs of training will be established when the military situation clears. Such programs will be an inspiration to officers to carry out their purpose to become proficient in surgery and to meet the requirements for fellowship in the College and for certification by the specialty boards. Officers, while receiving this training, will be on active duty with pay and emoluments, and they will have the benefit of almost constant association with the chiefs of services on full time duty in the hospitals. Such a program of training will facilitate expansion and reorganization of the Army, Navy and Veterans Administration by attracting temporary officers who are interested primarily in a surgical career.

If history is repeated the Presidential proclamation terminating the national emergency may be delayed as long as two years after the cessation of active military operations which, with the six months thereafter, as provided by existing law, will offer an excellent opportunity for graduate training in the service hospitals over a considerable period of time and will correspondingly ease the training load to be carried by civilian hospitals.

THE PUBLIC INTEREST—MEDICINE'S OPPORTUNITY

The prospects are that the postwar period will bring unprecedented demands for the services of surgical specialists. The first World War gave tremendous impetus to medical and surgical specialization. Today war medicine is again con-

tributing to enhanced appreciation of the value of the surgeon who has exceptional skill in a specific field. Aroused public interest is medicine's opportunity.

Special skills are best developed through systematic educational programs, in selected hospitals, whereby the fundamentals of medicine and surgery are mastered before training is narrowed and concentrated upon the specialty. Appreciation constantly grows of the necessity of understanding the functioning of the body as a whole before success can be expected in treating any part of it. The day is near when hospitals generally will extend privileges to practice a specialty in their institutions only to those who have had the requisite general and special training to insure competence. Many hospitals already limit privileges in this manner, no longer recognizing the physician who elects to practice surgery and the surgeon who elects to practice a surgical specialty without first obtaining the proper training in an approved institution.

The pivotal point in the training program is unquestionably the senior surgeon in the hospital which conducts graduate training in surgery. Upon his conscientious preceptorship the success of any plan will depend. There can be no substitution for the personal interest of the experienced surgeon in the progress of the learner. Hence the ultimate responsibility for the success of postwar graduate training will rest not alone upon hospital administrators and medical associations, but upon the Fellows of the College and other competent surgeons who assume personal responsibility for upholding high standards of training.

Leadership has been wisely exercised by the surgical profession and it is demonstrable that in the critical educational situation which now exists the American College of Surgeons is well prepared by its established program to direct the voluntary efforts of surgeons to apply effective remedies to overcome the losses sustained during the war. The teaching hospital is the essential instrumentality. We shall need many more.

The future of surgery is involved in the preparation for postwar world leadership in the healing arts as now planned and developed by physicians and hospitals in the American countries. The surgeon who helps his hospital to maintain or to inaugurate a program of graduate training in surgery under the wartime difficulties is rendering patriotic, scientific, educational, and humanitarian service, and is helping his profession and his hospital to build a firm foundation for public good will now and after the war.

SUBJECT INDEX TO VOLUME 80

ABDOMEN use of identifying "T" tube in common bile duct in gastric resection for duodenal ulcer adherent to bile ducts, 197 Transverse upper abdominal incisions, 641

Abnormalities, Congenital anomalies in region of umbilicus, 151 congenital, Defect of anterior mediastinum, successful surgical repair, 549

Abortion, Vitamin studies in, 139

Abcess, Acute pyrid, of lung, 351; of lung, Analysis of Massachusetts General Hospital cases of from 1938 through 1942, 568

Adolescent, Conservative management of slipping of capital femoral epiphysis, 324

Adrenal gland, Total pancreatectomy total gastrectomy total duodenectomy Splenectomy left adrenalectomy and omentectomy in diabetic patient, recovery, 352

Alcohol, Intravenous, sedative and analgesic, in surgical patient, preliminary report, 523

American College of Surgeons—1945 War Sessions deferred, 336 Graduate training in surgery and surgical specialties, 655

Amigen, Hemorrhagic shock, relative effect of amino acids, and gelatin in dogs, 181

Amino acid, Hemorrhagic shock, relative effect of amigen, and gelatin in dogs, 181

Amputation, war Practical considerations in definitive amputation surgery, 319

Amylase determinations, Pancreatic collections (pseudocysts) following pancreatitis and pancreatic necrosis, review and analysis of 10 cases, 325

Analgesia, caudal, Effect of continuous, upon uterine motility during labor study of 50 patients with Lördin tograph, 66

Anastomosis, Safe, simple and efficient method of intestinal, 636

Anatomy Surgical, of facial nerve, with special reference to parotid gland, 630

Androgen control therapy In 130 cases of carcinoma of prostate, 128

Anesthesia, alcohol, adjuvant in regional Intravenous, in surgical patient, preliminary report, 523

Aneurysm, Arteriovenous, ed. 217

Antiseptic, skin, Clinical appraisal of cetylpyridinium chloride as, 473 Clinical use of boric acid, ed. 651

Aorta, Arterial embolism, simplified technique for removal of saddle embolus at bifurcation of, with report of successful case, 509

Arm Practical considerations in definitive amputation surgery, 319

Army general hospitals, Surgical treatment of urinary obstruction in, 368

Artery Arterial embolism, simplified technique for removal of saddle embolus at bifurcation of aorta with report of successful case, 509

Aspiration biopsy Further studies on diagnosis of bone tumors by, 517

BACTERIA, Skin, their location with reference to skin sterilization, 174

Bacteriophage, Superiority of penicillin over sulfathiazole and certain other antibacterial substances, as indicated by experimental staphylococcal infections in chick embryos, 27

Bile ducts, Hepaticoduodenal intubation with hepatoduodenostomy for traumatic stricture of hepatic duct, 190

Use of identifying "T" tube in common, in gastric resection for duodenal ulcer adherent to, 197 Strictures of common and hepatic, ed. 555

Bladder Endometriosis of and ureter, 113 Surgical treatment of urinary obstruction in Army general hospitals, 368

Bleeding tendency Vitamin studies in abortions, 139

Blood, Hemorrhagic shock, relative effect of amino acids, amigen, and gelatin in dogs, 181; Use of red cells in transfusion therapy, 187 Absorbable oxidized cellulose with thrombin as hemostat in surgery, 470

Blood bank, Use of red cells in transfusion therapy, 187

Malaria from, transfusions, 261 Plasma, ed. 335

Blood vessels, War casualties from prolonged exposure to wet and cold, 1 Arteriovenous aneurysm, ed. 217, Functional pathology of experimental frostbite and prevention of subsequent gangrene, 346 Role of decompensatory reactions of peripheral, in tourniquet shock, 593 Treatment of thrombophlebitis, 615

Bone, transplantation, Rapid repair of defect of femur by massive, grafts after resection for tumors, 120; necrosis, Aseptic, of capital femoral epiphysis following adolescent epiphyseolysis, 199 tumors, Further studies on diagnosis of by aspiration biopsy, 517

Boric acid, Clinical use of, ed. 651

Breast, Hodgkin's disease of, 505 Roentgen therapy as adjunct in management of acute postpartum mastitis, 396 cancer Postoperative prophylaxis of recurrent, with testosterone propionate, 575

Burns, Further studies on preparation and use of sulfathiazole ointment in treatment of, 85 Statistical analysis of study of prevention of infection in soft part wounds, compound fractures, and, with special reference to sulfonamides, 263 Absorption of sulfonamides from, surface, 297 Nutrition of patients with thermal, 449 Mechanism of shock from, and trauma traced with radiosodium, 561

CALCIFICATION of tendon cuff of shoulder, 337

Cancer, of breast, Postoperative prophylaxis of recurrent, with testosterone propionate, 575

Carcinoma, metastasis, Spread of uterine and ovarian, with special reference to role of fallopian tube, 60 Multiple, of large intestine, 75 of prostate, Androgen control therapy in 130 cases of 128 Pancreaticoduodenectomy for primary 149, Pregnancy associated with, of large intestine, 211, of colon, producing acute intestinal obstruction during pregnancy, 545 Primary tumors of liver, 643

Cartilage, articular Aseptic necrosis of capital femoral epiphysis following adolescent epiphyseolysis, 199

Castration, Androgen control therapy in 130 cases of carcinoma of prostate, 128

Canalalgia, 631

Cellulose, oxidized, Absorbable, with thrombin as hemostatic agent in surgical procedures, 470

Cetylpyridinium chloride, Clinical appraisal of as skin antiseptic, 473

Chemotherapy, sulfa drugs, Analysis of Massachusetts General Hospital cases of lung abscess from 1938 through 1942, 568

Chest, Defect of anterior mediastinum, successful surgical repair, 549

Circulation, Functional pathology of experimental frostbite and prevention of subsequent gangrene, 346

- Colon, Multiple carcinomas of large intestine, 75 Surgery in obstinate megacolon radical one stage resection and ileocolicostomy 65 Pregnancy associated with carcinoma of large intestine. Carcinoma of producing acute intestinal obstruction during pregnancy, 545
- Cranium, Closure of defects of skull with tantalum, 303
- Current, Strength frequency curves in electrodiagnosis of experimentally produced peripheral nerve lesions in cat, 335
- Cyst, Pancreatic collections (pseudocysts) following pancreatitis and pancreatic necrosis, review and analysis of 5 cases, 225

DEFORMITIES, congenital. Simplified design for repair of single cleft lip, 3

Deboveilber's fascia, Anatomical and surgical study of 373

Diabetes, Total pancreatectomy total gastrectomy total duodenectomy splenectomy left adrenalectomy and omentectomy in a diabetic patient, recovery 353

Diagnosis, Strength frequency curves in electrodiagnosis of experimentally produced peripheral nerve lesions in cat, 335 preoperative, Pantopaque myelography as aid in, of protruded intervertebral discs, preliminary report, 357 aspiration biopsy Further studies on, of bone tumors by 317

Dicumarol, Influence of thyroid principle on prothrombinolytic action of 178

Diet, high caloric, high vitamin, Nutrition of patients with thermal burns, 449

Disc, intervertebral, Pantopaque myelography as an aid in preoperative diagnosis of protruded, preliminary report, 357

Dressings, Further studies on preparation and use of sulfathiazole ointment in treatment of burns, 85

Duodenum, carcinoma of Pancreatoduodenectomy for 49 Hepatoduodenal intubation with hepatoduodenostomy for traumatic stricture of hepatic duct, 100 ulcer Use of identifying "T" tube in common bile duct in gastric resection for adherent to bile ducts, 97 Total pancreatectomy total gastrectomy total duodenectomy splenectomy left adrenalectomy and omentectomy in diabetic patient, recovery 35 Gastric resection for duodenal ulcer 355 Acute peptic ulcers following distant operations, 40

EDUCATION, medical, Total abdominal hysterectomy and occasional operator 519 medical, Graduate training in surgery and surgical specialties, 655

Elbow Active motion by means of occupational therapy in treatment of fractures, 361; Internal epicondylar epiphysis and, injuries, 416

Electrodiagnosis, See diagnosis

Embolism, Arterial, simplified technique for removal of saddle embolus at bifurcation of aorta. 11th report of successful case 309 Treatment of thromboembolism, 65

Endometriosis, of bladder and ureter 3

Epiphysis, capital femoral, Aseptic necrosis of, following adolescent epiphyseolysis, 100 capital femoral, Conservative management of adolescent slipping of 324; Internal epicondylar and elbow injuries, 40

Exophthalmos, Influence of thyroidectomy on prominence of eyes in guinea pig and in man, 346

Exposure, War casualties from prolonged, to wet and cold, 1; Extremities, War casualties from prolonged exposure to wet and cold, 1; Causalgia, 63

Eyes, prominence of, Influence of thyroidectomy on, in guinea pig and in man, 346

FALLOPIAN tube, Spread of uterine and ovaries carcinoma with special reference to role of 60

Fascia, Tumors of subcutaneous tissue and, 11th special reference to fibrosarcoma, clinical study 300

Femur neck of Roentgenographic interpretation of what constitutes adequate reduction of, fractures, 471; Rapid repair of defect of, by massive bone grafts after resection for tumors, 120; Aseptic necrosis of capital femoral epiphysis following adolescent epiphyseolysis, 100 Conservative management of adolescent slipping of capital femoral epiphysis, 324; fracture of neck, Treatment of postoperative infections following internal fixation for 479

Fistula, Arteriovenous aneurysm ed. 317

Flap, Mirlault, Simplified design for repair of single cleft lip, 3

Fluids, parenteral, Effects of on metabolism of electrolytes during postoperative convalescence, 609

Fluid loss, Role of decompensatory reactions of peripheral blood vessels in tourniquet shock, 593

Foot, gangrene, War casualties from prolonged exposure to wet and cold, 1

Fractures, Roentgenographic interpretation of what constitutes adequate reduction of femoral neck, 471; compound, Statistical analysis of study of prevention of infection in soft part wounds and burns with special reference to sulfonamides, 463 Active motion by means of occupational therapy in treatment of, for Treatment of postoperative infections following internal fixation for neck of femur 479

Frostbite, War casualties from prolonged exposure to wet and cold, 1; Functional pathology of experimental, and prevention of subsequent gangrene 346

GALL bladder disease of Evaluation of clinical significance of serum amylase and lipase determinations, 415 Gangrene, functional pathology of experimental frostbite and prevention of subsequent, 346

Gas infection, War casualties from prolonged exposure to wet and cold, 1

Gastrectomy Total, report of 8 cases, 534

Gastrointestinal tract, Adding more safety to, anterior, 407 Total gastrectomy, report of 8 cases, 534

Gelatin, Hemorrhagic shock, relative effect of amino acids, amine, and, in dogs, 181

Gitter exophthalmic, Influence of thyroidectomy on prominence of eyes in guinea pig and in man, 346

Grafts, nerve, Experimental studies of peripheral nerve injuries. III. Study of recovery of function following repair by end to end sutures and, 351; bone, Rapid repair of defect of femur by massive, after resection for tumors, 120 dermal, Reporative plastic surgery of secondary cleft lip and nasal deformities, 417 nerve, Peripheral nerve surgery ed. 444

HAND, Active motion by means of occupational therapy in treatment of fractures, 361

Harelip, Reporative plastic surgery of secondary cleft lip and nasal deformities, 417

Heart, Arteriovenous aneurysm, ed. 317

Hemostasis, Absorbable oxidized cellulose with thrombolytic as hemostatic agent in surgical procedures, 470

Hepatic duct, See bile ducts

Hernia, inguinal, Fascia-patch transplant in repair of, 411

Hip, Roentgenographic interpretation of what constitutes adequate reduction of femoral neck fractures, 471; Conservative management of adolescent slipping of capital femoral epiphysis, 324; Treatment of postoperative infections following internal fixation for fracture of neck of femur 479

- Hodgkin's disease, of breast, 305
 Humerus, Internal epicondylar epiphysis and elbow injuries, 416
 Hydrocephalus, classification and plastic repair of ureteropelvic obstructions, 485
 Hysterectomy Total abdominal, and "occasional operator" 539
- INCISIONS**, Transverse upper abdominal, 647
 Infections, staphylococcal, Superiority of penicillin over bacteriophage, sulfathiazole and certain other antibacterial substances, as indicated by experimental in chick embryos, 27 Further studies on preparation and use of sulfathiazole ointment in treatment of burns, 85 Effect of sulfanilamide and sulfathiazole on human tissue, 143 Statistical analysis of study of prevention of in soft part wounds, compound fractures, and burns with special reference to sulfonamides, 263 postoperative, Treatment of following internal fixation for fracture of neck of femur 479
 Injuries, peripheral nerve, Experimental studies of III. Study of recovery of function following repair by end to end sutures and nerve grafts, 35 Mechanism of shock from burns and trauma traced with radiosodium, 561
 Instruments and apparatus, Terhear respirator War casualties from prolonged exposure to wet and cold, 1 Lörind tograph, Effect of continuous caudal analgesia upon uterine motility during labor study of 50 patients with, 66, Soutter apparatus, Roentgenographic interpretation of what constitutes adequate reduction of femoral neck fractures, 97 Bokdry splint, Supportive immobilization of cervical spine, 107 arthrometer Active motion by means of occupational therapy in treatment of fractures, 361 for measuring range and speed of knee extension, ratios of tension in quadriceps and patellar tendons to resistance at ankle, Function of patella and effects of its excision, 389 tourniquet type clamp, Arterial embolism, simplified technique for removal of saddle embolus at bifurcation of aorta with report of successful case, 509 aspiration biopsy set, Further studies on diagnosis of bone tumors by, 517 for measuring intercorneal distance, Influence of thyroidectomy on prominence of eyes in guinea pig and in man, 526
 Intestine, large, Multiple carcinomas of 75 large, Pregnancy associated with carcinoma of 211 Gastric resection for duodenal ulcer 355, obstruction, Carcinoma of colon, producing acute, during pregnancy, 543, anastomosis, Safe, simple and efficient method of 636
- JAUNDICE**, late, Nutrition of patients with thermal burns, 449
 Joint ranges, Active motion by means of occupational therapy in treatment of fractures, 361
- KIDNEY** Surgical treatment of urinary obstruction in Army general hospitals, 568, pelvis of Hydronephrosis, classification and plastic repair of ureteropelvic obstructions, 485
 Knee, Function of patella and effects of its excision, 389
- LABOR**, Effect of continuous caudal analgesia upon uterine motility during, study of 50 patients with Lörind tograph, 66
 Leg, Practical considerations in definitive amputation surgery 319
 Lips, Cleft, Simplified design for repair of single, 12 cleft, Reporative plastic surgery of secondary and nasal deformities, 423
- Liver Hepaticoduodenal intubation with hepaticoduodenostomy for traumatic stricture of hepatic duct 190 disease of Evaluation of clinical significance of serum amylase and lipase determinations, 435 Primary tumors of 643
 Lung, abscess, Acute putrid, 351 abscess, Analysis of Massachusetts General Hospital cases of from 1938 through 1942 568, Treatment of thrombophlebitis, 615
 Lymphogranuloma, Hodgkin's disease of breast, 305
- MALARIA**, from bank blood transfusions, 261
 Martin, Isabelle Hollister (1865-1945) ed. 555
 Massachusetts General Hospital, Analysis of cases of lung abscess from 1938 through 1942, 568
 Mastitis, postpartum Roentgen therapy as adjunct in management of acute, 396
 Mediastinum, Defect of anterior successful surgical repair 549
 Medical corps, U S Army Russian, United States Army Medical Corps, ed. 333 U S Army Mission of surgical specialists in, ed. 441 U S Army cor 448
 Medicine, military organization, Role of specialist in, ed. 109 cor 448 Malaria from bank blood transfusions, 261 military, Statistical analysis of study of prevention of infection in soft part wounds, compound fractures, and burns with special reference to sulfonamides, 263 war Surgical treatment of urinary obstruction in Army general hospitals, 568
 Megacolon, Surgery in obstinate, radical one stage resection and ileosigmoidostomy 164
 Menstruation, effect of testosterone propionate, Postoperative prophylaxis of recurrent mammary cancer, 575
 Mortality fetal, maternal, Pregnancy associated with carcinoma of large intestine, 211
 Muscle, degenerating Strength frequency curves in electrodiagnoses of experimentally produced peripheral nerve lesions in cat, 235
- NERVE**, peripheral, Experimental studies of, injuries. III. Study of recovery of function following repair by end to end sutures and, grafts, 35 peripheral, Strength frequency curves in electrodiagnoses of experimentally produced, lesions in cat, 235 Peripheral, surgery ed. 444, facial, Surgical anatomy of with special reference to parotid gland, 620 peripheral, median, sciatic, Causalgia, 631
 Nitrogen balance, Nutrition of patients with thermal burns, 449
 Nose, Simplified design for repair of single cleft lip, 12 deformities, Reporative plastic surgery of secondary cleft lip and, 422 Slickle flap for nasal reconstruction, 497
 Nutrition of surgical patient, Intravenous injection of protein digest solution in, 313, of patients with thermal burns, 449 Intravenous alcohol in surgical patient, preliminary report, 523
- OBSTETRICS**, Roentgen therapy as adjunct in management of acute postpartum mastitis, 396
 Occupational therapy Active motion by means of in treatment of fractures, 361
 Omentum, Total pancreatectomy total gastrectomy total duodenectomy, splenectomy left adrenalectomy and omentectomy in diabetic patient, recovery 252
 Ovary Spread of uterine and ovarian carcinoma with special reference to role of fallopian tube, 60
- PAIN** Causalgia, 631
 Palate, cleft, Reporative plastic surgery of secondary cleft lip and nasal deformities, 423

Pancreas, Pancreaticoduodenectomy for primary carcinoma of duodenum 149 Pancreatic collections (pseudocysts) following pancreatitis and pancreatic necrosis, review and analysis of 10 cases, 225 Total pancreaticotomy total gastrectomy total duodenectomy splenectomy left adrenalectomy and omentectomy in a diabetic patient, recovery 252 Disease of Evaluation of clinical significance of serum amylase and lipase determinations, 435

Pancreaticoduodenectomy for primary carcinoma of duodenum, 149

Pantopaque myelography as aid in preoperative diagnosis of protruded intervertebral discs, 257

Parotid gland, Surgical anatomy of facial nerve, with special reference to, 620

Patella, Function of and effects of its excision 349

Pelvis, Anatomical and surgical restudy of Denonvilliers fascia, 373

Penicillin, Superiority of over bacteriophage sulfathiazole and certain other antibacterial substances, as indicated by experimental staphylococcal infections in chick embryos 7

Peritoneum, Anatomical and surgical restudy of Denonvilliers fascia, 373

Physical therapy Calcification of tendon cuff of shoulder 337

Plasmodial cyst, sinus, their management and operative treatment, 69

Plasma, ed. 335

Plasma prothrombin time Influence of thyroid principle on prothrombolytic action of dicoumarol, 178

Plasma volume Mechanism of shock from burns and trauma traced with radioisotopes, 56

Pleural space Defect of anterior mediastinum, successful surgical repair 549

Poisoning, accidental, Clinical use of boric acid, ed. 651

Postoperative care of recurrent mammary cancer with testosterone propionate, 575

Postoperative convalescence Effects of parenteral administration of fluids on metabolism of electrolytes during 609

Pregnancy Vitamin studies in abortions, 39 associated with carcinoma of large intestine, 2 Carcinoma of colon, producing acute intestinal obstruction during, 543

Prostate carcinoma of, Androgen control therapy in 30 cases of, 281 Anatomical and surgical restudy of Denonvilliers fascia, 373

Protein digest solution, Intravenous injection of in surgical patients, 215

Prothrombin time, Vitamin studies in abortions, 39

Psychiatric analysis, Cataplexia 63

RADIOIODINE, Mechanism of shock from burns and trauma traced with radioisotopes, 56

Rectum, Multiple carcinomas of large intestine 751 Anatomical and surgical restudy of Denonvilliers fascia, 373

Red cells, Use of in transfusion therapy 87

Röntgen therapy, as adjunct in management of acute post-partum mastitis, 306

SEMINAL vesicles, Anatomical and surgical restudy of Denonvilliers fascia, 373

Serum amylase, Evaluation of clinical significance of and lipase determinations, 435

Serum lipase, Evaluation of clinical significance of serum amylase and determinations, 435

Shock, Hemorrhagic, relative effect of amino acids, amigen and gelatin in dogs, 181 Mechanism of, from burns

and trauma traced with radioisotopes, 56; traumatic, Role of decompressory reactions of peripheral blood vessels in, 593

Shoulder tendon cuff of Calcification of 337

Skin, bacteria, their location with reference to, strains 174 Clinical appraisal of cetylpyridinium chloride as, antiseptic 473

Skin grafts, N. trition of patients with thermal burns, 447

Skull, See cranium

Soap and ter knobol and ether Clinical appraisal of cetylpyridinium chloride as skin antiseptic, 473

Sodium contents of normal tissues, Mechanism of shock from burns and trauma traced with radioisotopes, 56

Specialist, Role of, in military medicine, ed. 109, cor. 414

Spleen, Total pancreaticotomy total gastrectomy total duodenectomy splenectomy left adrenalectomy and omentectomy in diabetic patient, recovery 252

Sterilization, of skin, Skin bacteria, their location with reference to, 174

Stomach, Use of identifying "T" tube in common bile duct in gastric resection for duodenal ulcer adherent to life ducts, 97 Total pancreaticotomy total gastrectomy total duodenectomy splenectomy left adrenalectomy and omentectomy in diabetic patient, recovery, 252

Gastric resection for duodenal ulcer, 355 ulcer Acute, following distant operations, 410 Total gastrectomy, report of 8 cases, 534

Strictures, of common and hepatic bile ducts, ed. 555

Sulfanilamide Effect of and sulfathiazole on leucine time, 143

Sulfathiazole Superiority of penicillin over bacteriophage and certain other antibacterial substances, as indicated by experimental staphylococcal infections in chick embryos, 27 emulsion ointment, Further studies in preparation and use of in treatment of burns, 45

Effect of sulfanilamide and on human tissue, 143

Sulfonamides, Statistical analysis of study of prevention of infection in soft part wounds, compound fracture, and burns with special reference to, 263, Absorption of from burn surface 307

Surgeon General, of Army and Navy organization of office of, Role of specialist in military medicine, ed. 109, cor. 418

Surgeon, training of Total abdominal hysterectomy and occasional operator 539

Surgery military War casualties from prolonged exposure to wet and cold, plastic, Simplified stages of repair of single cleft lip, 2 Experimental studies of peripheral nerve injuries, III. Study of recovery of function following repair by end to end sutures and nerve grafts, 33 military Plasmodial cyst and sinus, their management and operative treatment, 69 method. Hepaticoduodenal intubation with hepatoduodenotomy for traumatic stricture of hepatic duct, 102

military Role of specialist in, ed. 109, cor. 415, method, one stage megacolon resection and ileocolicostomy in obstinate megacolon, radical, 44; method. Use of identifying "T" tube in common bile duct in gastric resection for duodenal ulcer adherent to life ducts, 1071 Aseptic necrosis of capital femoral epiphysis following adolescent epiphyseolysis, 90 plastic fascia-patch transplant in repair of hernia, 243, military Closure of defects of skull with tantalum, 305

Intravenous injection of protein digest solution in surgical patients, 33 amputation, Practical considerations in definitive, 319; military United States Army

Medical Corps, ed. 333 war Plasma, ed. 335 Acute purulent abscess of lung, 351 technique, Pfannenstiel incision, Suspension of uterus using, 404 technique, modified Connell suture, Adding more safety to gastrointestinal sutures, 407 plastic, Reparative, of secondary cleft lip and nasal deformities, 422 military Mission of surgical specialists in U. S. Army ed. 441 military Peripheral nerve, ed. 444 technique, Absorbable oxidized cellulose with thrombin as hemostatic agent in surgical procedures, 470 pyeloplasty, Hydronephrosis, classification and plastic repair of ureteropelvic obstructions, 485, plastic, Sickle flap for nasal reconstruction 407 technique, Total gastrectomy, report of 8 cases, 534, technique, Defect of anterior mediastinum successful surgical repair 540 technique, Strictures of common and hepatic bile ducts, ed. 535 postoperative care, Effects of parenteral administration of fluids on metabolism of electrolytes during, 600 technique, Safe, simple and efficient method of performing intestinal anastomosis, 636 technique, Transverse upper abdominal incisions, 641 war Graduate training in surgery and surgical specialties, 655

3. sympathectomy Causalgia, 631

THE PREPONDERANCE OF GALLSTONES IN WOMEN

An Etiological Study

II E. ROBERTSON M D Rochester Minnesota

IN studies on the occurrence of gallstones one of the few facts on which almost all authors are agreed is that women are more frequently subject to gallstone disease than are men.¹ This conclusion is one of the outstanding features encountered in any review of publications about gallstones. In a recent paper on 'Pregnancy and Gallstones' by Robertson and Dochat statistical data on this subject were recorded and reviewed. Among the patients of the Mayo Clinic women's susceptibility to the formation of gallstones when compared with that of men gave the proportion of 1.8 to 1 and in a combined summary of reports of similar statistics from 22 writers, this proportion was found to be 2.2 to 1. The usual explanation offered to account for this fact was that pregnancy favored the occurrence of gallstones, but the authors just cited after a fairly complete review of this question concluded there was considerable doubt as to the validity of the theory that childbearing could wholly account for the preponderance of gallstones in women. Consequently some other solution appears to be necessary and the present study is presented with that end in view.

A detailed examination of all the theories which have been proposed to explain the presence of gallstones would lead too far afield. However a brief review of the salient elements of these theories may lead toward a more nearly correct orientation with the main problem.

The only notable exception to this statement is found in a paper by Miyake and Ishiyama (1930). They endeavored to prove that the increased tendency toward the production of gallstones among European and American women, as compared with men, was due to their custom of wearing corsets, as the Japanese women, who did not wear corsets, had no higher incidence, they asserted, than did men. However the figures of other Japanese writers do not support this contention.

Section on Pathological Anatomy Mayo Clinic, Rochester Minnesota.

tation with the main problem. Such an effort at once encounters the usual difficulties. It is not only confusing but also astonishing to see how much authors diametrically disagree as to the significance of the data they have collected. No single cause (or even multiple causes) has proved to be a satisfactory explanation for the formation of gallstones, although writers have placed varying emphasis on one or more of what they frequently designate as *predisposing influences*. For simplification I have elected to discuss these under the following headings: (1) stasis of bile, (2) changes in the constituents of bile, (3) infection, (4) associated diseases and constitutional susceptibility, and (5) neurogenic disturbances.

STASIS OF BILE

Almost as early as gallstones were recognized the theory was advanced that they were due to the too prolonged retention of bile in the gall bladder. In the middle of the sixteenth century pathological stasis of bile was emphasized by Fernel when he wrote "They [gallstones] come from bile that is held back too long is not emptied or not renewed." Coe, in 1757 asserted stagnation and inspissation of bile, particularly in women accounted for women's greater liability to acquire gallstones. Nearly a century later (1842) Rokittansky concluded that gallstones were the result of stagnation and the holding back of bile. Meckel von Hemsbach (1856) similarly agreed that no gallstones could be formed "if the factor of stagnation was absent." Kraus (1881) stated that an intermediate cause of gallstones was a slowing of the flow of bile into the intestine and a resultant *Anhäufungen* (accumulation) of bile in the gall bladder and Cohnheim (1882) referred gallstones to a difficulty in the emptying of the gall bladder.

Marchand (1888) made the broad generalization that everything which led to thickening of the bile obstruction of the bile ducts or insufficient emptying resulted in granular (koernigen) deposits from which larger concretions might readily be formed. Klebs (1889) asserted that "the preliminary condition [*Vorbedingungen*] for gallstones is stagnation of bile." Naunyn (1891) wrote, "Stasis is the decisive cause of gallstones and Stagnation of the bile remains the only well established cause of the formation of gallstones." Luetkens asserted that Naunyn's most important contribution to the etiology of gallstones was the idea that stasis was a *conditio sine qua non* for gallstones. Other prominent authors, including Welts (1894) Gumprecht (1895) Aschoff and Baumeister (1909) Grube and Graß (1912) Aoyama (1914) and Meltzer (1917) reached similar conclusions. Later writers were equally impressed by the importance of this factor. For example Rous and McMaster (1921) stated, "Intermittent biliary stasis is admittedly the principal predisposing cause of cholelithiasis, while Chaulffard (1922) appeared certain that stasis, no matter what the cause favored changes in solubility due to overconcentration of cholesterol and consequent precipitation." Again in 1924 Rous, Drury and McMaster (1924) wrote that stasis leads "to accumulation of organic debris." Whitaker (1927) was equally emphatic in the statement "The fundamental condition then to gallstone formation is universally recognized to be stasis," and in 1929 (221) under the title Biliary stasis as a factor in the production of gallstones he said "On the whole recent studies confirm the old opinion that stasis is an essential factor in gallstone formation. Again in 1934, Whitaker (222) echoed Fernel in the conclusion, "Any condition in which the bile remains an abnormally long time in the gallbladder predisposes to gallstone formation and finally stated, "Practically all students of the subject have agreed that one factor necessary to gallstone formation is stasis either in the gallbladder or ducts." Westphal (227) in 1922 also asserted that in man stasis without infection or bacteria could lead to precipitation of bilirubin and cholesterol while Schaefer (1932) expressed almost the same opinion when he stated, "The principal factor (in the precipitation of cholesterol) is concentration by absorption of fluid and stasis is the usual cause of this." Finally in a late edition (1938) of Osler's "Text book of Medicine" the statement is made that "all conditions favoring stasis predispose [to gall stones]"

Naturally enough, the conditions which might conceivably produce stasis have received early and repeated consideration. Mechanical factors, such as anatomic peculiarities of the biliary tract, increased intra-abdominal tension (especially during pregnancy) pressure on (or distortion of) the bile ducts by the pregnant uterus, and relaxation of the abdominal walls producing ptosis of viscera² after pregnancy frequently have been mentioned. The theory first proposed by Heidenhain in 1863 namely that the normal respiratory movements of the diaphragm served as an adjunct to the drainage of the biliary system including emptying of the gall bladder and the conclusion that increased abdominal pressure, as in pregnancy interfered with this function, have had many advocates, even as late as 1932 when Blood supported this view. Other careful investigators have failed to confirm these notions.

Klebs in 1872 and Marchand in 1888 called attention to the fact that at postmortem examinations, a transverse groove across the right lobe of the liver was occasionally found. This was noted particularly in women and was called "Schnurleber." It was ascribed to the tightly laced corsets prevalent among women at that time. Several later writers agreed with Marchand that this custom favored the stasis of bile and, thus, the formation of gallstones.³ As tight lacing became less customary this theory was, perforce, abandoned.⁴ In support of other factors assumed to result in biliary stasis, frequent references were made to the alleged sedentary habits of women,⁵ to obesity and to old age.

Some writers, however have minimized the role which stasis might play in the etiology of gallstones. Thus Schade (1910) concluded that, although stasis of bile in the gallbladder was a very important factor in the precipitation of cholesterol from the bile, this precipitated cholesterol was not identical with the formation of calculi, and that other influences seemed to be necessary. A few authors even denied that stasis was of any particular moment. Hein as early as 1846, made the shrewd observation that "Ruhe (rest) alone was not sufficient to produce gallstones, as the bile reg-

²Harrold (1922), as the result of direct observation during abdominal operations, stated, "There was very rarely complicated by ptosis."

³The same deformity of the liver occasionally found in men, was supposed to be caused by tight belts, particularly the sword belts of military men (Manser, 1891), and a similar reference was pronounced to result from the use of the corset (Marchand, 1888).

⁴And yet as Marchand (1888) the following quotation from Meyer (1909) appeared in prominent medical journals: "Any limitation in the flow of bile may result in various gallstone troubles. The year round use of anything tight around the abdomen. A lady wears too tightly around the middle, or girdle that is worn too tight in the worst time because she is."

⁵Osler-Snyder recorded that J. P. Frank, in 1872, noted that obesity and ptosis were supposed to favor gallstones, and Bock, in 1879, noted that literary men, priests, and persons who were sedentary were all prospective subjects for gallstones.

⁶Gumprecht wrote "besides stasis there is no other single cause of gallstones."

larly undergoes short periods of Ruhe during inactivity of the intestine. Sixty-eight years later (1914) Lichtwitz asserted that the idea of stasis as a factor in the production of gallstones was not surely established. Rovsing (1923) noted that Aschoff had accepted stasis as "an irrefutable fact" ("eine unerschütterliche Tatsache") and that from this one would conclude there was a large amount of convincing proof behind it. Unfortunately he added one seeks in vain for any such evidence. Rovsing also noted that acquired obstructing biliary lesions in man did not necessarily produce gallstones. Gundersmann (78) wrote in 1926 "The idea of stasis is entirely hypothetical and said that it would be better to drop completely this uncertain theory." Mentzer (1927) stated that stasis of bile was not essential for gallstone formation and Schmidt (1930) agreed with Gundersmann that the theory of stasis was somewhat hypothetical. Newman was more emphatic when in 1933 he wrote "Stasis in itself is no explanation for anything" he also said "The magic word stasis on analysis disappears from the list of primary causal factors [of gallstones]" while Andrews (1933) adopted this opinion by stating "There is no evidence that stasis alone is a factor." In 1935 Pavel asserted "The theory of the corset, atony of old age and other causes of stasis have failed [to explain gallstones] and added "The history of the corset as a cause of stasis and lithiasis represents a symbol of the role of inertia in the maintenance of old theories. Also in 1936 in the second edition of their book on "La vesicule biliare, Chury and Pavel expressed doubts about the importance of stasis in the production of gallstones as they had frequently observed stasis both experimentally and clinically without finding gallstones. Greene and his coworkers (1936) agreed with Andrews that biliary stasis alone is insufficient to produce calculi. Eppinger (1937) flatly asserted "Stasis alone never leads to cholelithiasis" (Stauung allein führt nie zu Cholelithiasis). In 1939 Carter, Greene and their colleagues reported that they found biliary stasis present to an equal degree in noncalculous and in calculous gall bladders and stated "While there is strong presumption that stasis was of importance in the formation of gallstones, other unknown factors must also have been in operation."² Finally Galland

and Baker in 1940 asserted that neither biliary stasis nor stasis in the pancreas is a single factor producing gallstones.

Summary Although stagnation of any fluid in which precipitation of its elements is to take place would appear to be a necessary requirement this factor does not seem to play an important role in the formation of gallstones. As Hein pointed out in 1846 the bile normally undergoes periods of quiescence. The length of such periods is determined largely by the quality of the ingested food as well as by the normal digestive functions of the upper part of the gastrointestinal tract. Even during the times of active evacuation it is probable that the gall bladder frequently is not completely emptied. During its stay in the gall bladder the bile is concentrated up to about a tenth of its original volume because of active absorption of water and water-soluble salts. This natural quiescence of bile in the gall bladder can hardly be accused of giving rise to gallstones, and repeated observations indicate that abnormal stasis created by such obstructive phenomena as lodgment of a calculus in the cystic duct, or carcinoma or stones in the common bile duct never produces, or even favors, the production of gallstones. Stasis so useful in the laboratory test tube experiment, is not the cause of gallstones.

CHANGES IN BILE

Although there is no evidence that Paracelsus (1493-1541) had any intimate knowledge of gallstones (or of any other pathological condition for that matter) his was the earliest attempt to establish a chemical cause for certain diseases.³ What he denominated as "tartaric processes" was the basis for a doctrine of calcification and concretion formation and was applied by him to all sorts of calcific deposits as well as to calculi. According to Muleur he included sediments in the cavities of the body such as the urinary bladder and the channels of the liver. In his *Opera Paramirum* published in 1572 the following sentence occurs, "Now however the bile contains this same Tartarum and it thus happens that in the bile lies the material for stones." Plater (1536-1614) compared gallstones to stalactites and spoke of a foreign substance which modified the constitution of the bile. Thenard (1821) thought the precipitation of bile pigment came from a diminution of Natron (alkaline salts) and Seifert (1851) inferred that increase of lime in the drinking water was important. However Thudichum (1863) is

¹Ich glaube man setzt drei Ursachen zusammen Begriff ganz fallen zu lassen. (Greene, 1936)

²In their book on changes of the biliary tract, published in 1939, these same authors wrote on page twenty-four, "Calculi have been observed under conditions which seem to preclude the presence of stasis." Two pages farther on, in discussion of the hypertrophic gall bladder, they stated, "The concept of stasis explains many of the clinical features of the disease. First, on page forty-two, they said, 'In patients with typical gall-bladder symptoms, the stone located in the gallbladder, but palpation in the abdomen results of stasis, and the most frequent accompaniment of gallstones in operative specimens.'

³Alfleur (1846) called Paracelsus "the first popularizer of the general pathology of diseases," while Lutz (1923) said he was "the great searchlight of the medical Renaissance."

usually given credit for being the first to express a more rational theory—namely, that fermentation (Gaerung) of bile caused a precipitate by splitting the bile acids and alkalies. The pathologist Klebs, whose views on many phases of disease were far ahead of his time, wrote in his "Allgemeine Pathologie" (1889) that although the presence of gallstones furnishes many perplexities, nevertheless one thing is sure, namely that they arise from a metamorphosis of the normal constituents of the bile.

In 1789 De Fourcroy made known the discovery of cholesterol and asserted that all human gallstones contained this substance. It was given its present name by Chevreul (38, 39) in 1815 and 1816 and in 1821 Thenard assigned to it the principal role in the formation of gallstones. Since then there have been innumerable attempts to determine the conditions which govern the normal and pathological metabolism and the fate of this very important substance, particularly in its relation to bile and gallstones. Both speculations and experiments have been freely employed to explain why it is normally kept in solution in the bile and what circumstances intervene to cause its precipitation. With the identification of bile acids, first about the middle of the nineteenth century the suspicion arose that these acids and their salts were concerned in keeping the cholesterol of the bile in solution. Klebs (1889) expressed this view when he stated: "Cholesterin is held in solution by the bile acid salts and can only be precipitated when these [salts] are diminished." Many others have confirmed this statement, especially Andrews and his colleagues (1932) who demonstrated that by dialysis *in vitro* bile salts will pass through a semipermeable membrane and leave cholesterol deposits behind. Andrews and his associates (1933) further agreed with previous authors that "no substance other than bile salts in the bile is capable of holding cholesterol in solution."

It is suggested by many workers. Some were able to demonstrate a slight increase of cholesterol in the blood in the later months of pregnancy but it was not clearly evident that hypercholesteremia, from any cause, uniformly affected to any important degree the cholesterol content of the bile or what is more important, the production of gallstones. Similarly, feeding experiments gave contradictory results, although it appears probable that a persistently high fat (or high protein) diet increases the amount of biliary cholesterol. All of the experiments and observations in the field represent a sort of groping after the cause of gallstones. Many workers have been convinced that once a consistent increase of cholesterol in the blood or bile from any cause can be demonstrated, that cause would have an important bearing on the production of gallstones. Among others, Carter and his associates (34) and Rehfuess and Nelson advised a diet low in cholesterol as a routine treatment for persons who have, or may have, gallbladder disease. But the increase or decrease of cholesterol in the blood or bile from any cause has assumed relative unimportance as long as the proper ratio (of solubility) between bile salts and cholesterol could be maintained.

In 1927 Herzheimer wrote, "The question of nuclei is the principal problem of gallstones. The well known tendency of some substances in solution particularly crystalloids to agglutinate around some sort of a central core (or nucleus) undoubtedly was responsible for the widely held notion that biliary constituents, especially cholesterol and bile pigments, could precipitate and collect around inert substances. These have been variously described as clumps of bacteria, epithelial and other cellular debris, pigment particles, intrahepatic bile-duct concretions, cholesterol polyps, or masses of mucus. Numerous and largely unsuccessful attempts were made to produce gallstones by implanting foreign bodies in the gall-

Closely associated with the concept of a nucleus is the supposition of some kind of a binding substance. Hippocrates and Galen are said (Weiser and Gray 213) to have recognized this possibility and von Heyde in 1684 extracted the crystal line material from a urinary calculus and observed a residual framework. For many authors, mucus appeared to fulfill the requirements for a central core as well as a cement substance. Kemp of London in 1856 stated "The mucus of the gall bladder is not merely a secretion designed to lubricate the interior of that organ and protect it from irritation by its other contents but it is an essential and integral portion of cystic bile. In that same year Meckel von Hemsbach concluded "Two basic factors underlie the formation of every true gall or urinary stone: first the presence of an organic substance, mucus, in which there may be deposition of salts; second a suitable urinary or bile fluid to serve as the mother liquor for these sediments. The decomposable organic substance, mucus, is unquestionably necessary. Stones are formed only when an organic binder is carried down too. Eighty-four years later (1940) Alvarez expressed a similar conclusion when he wrote "It is well known that the mucous membrane of the gall bladder secretes a small amount of viscid alkaline mucus. This probably causes trouble at times by serving as a cement for the formation of gallstones.

However Aschoff (1905) could not obtain a positive staining reaction for mucus in the mucosa of the normal gall bladder. He thought there might be a special kind of mucin or some "Vorstußen" (antecedent) to mucin. Chiray and Pavel (1936) likewise were puzzled, because they said "One cannot find specifically staining mucus in the bile. They referred to Wahlgren who in 1901 had determined that the cells of the mucosa of the human gall bladder secrete not mucus, a glycoprotein, but a mucinlike material nucleoprotein (or nuclealbumin) which differed from true mucin by the absence of a reducing substance. Wahlgren thought true mucin probably arose in man from the epithelium of the bile ducts as he always found mixtures of true mucin and nuclealbumin in human gall bladders. With this conclusion Hammarsten (1905) who wrote extensively on this subject was in full agreement. But Polcard (1922) stated that while properly speaking there are no true mucus glands in the gall bladder nevertheless its cells can readily take over the function of producing mucus just like the intestinal epithelium. Each cell of the epithelium (of the gall bladder) can secrete (mucus) and does so to a variable extent. Johnson (1922)

maintained, "The epithelial cells of the gallbladder mucosa secrete mucus more abundantly in proportion to the surface than any other [group of] mucus secreting cells. Harding studied the subject in 1934 and agreed with Polcard and also noted a similar opinion by Jurisch in 1910. Harding claimed to have found in the epithelial cells of normal gall bladders mucous granules which stained well with mucicarmine. Finally Ivy (1934) in a review of the physiology of the gall bladder said, "The gallbladder secretes a viscid colorless secretion its viscosity being due to protein rather than to true mucin, which if present, is only in traces.

Aschoff in 1906 and in 1913 referred to what he and others including Flandin (1912) called the Erweisskelette or Erweisgeruest (albuminous framework) of gallstones, which Kuru who worked under Aschoff concluded was fibrin. This albuminous substance was presumed to enter the bile either in the form of an inflammatory exudate or as an abnormal product of injured liver cells, and to produce albuminocholia, which was emphasized by Lichtwitz (125) as comparable in some respects to the albuminuria of pregnancy.

In the fifth edition of Wells' "Chemical Pathology" are found the following broad generalizations. All pathological concretions appear to be laid down according to a definite law. There must first be a nucleus of some substance different from the substance that is to be deposited and which is most frequently a mass of desquamated cells but may consist of clumped bacteria, masses of mucus precipitated protein or a foreign body of almost any sort. Upon this nucleus, substances crystallize out of a solution much as cane sugar crystallizes on a string to form rock candy but with the important exception that among the crystals is usually deposited more or less mucin or other organic substance which forms a framework in which the crystals lie and which remains if the crystals are dissolved out as a more or less perfect skeleton of the concretion. In no case would the concretion form were it not that the solution is overcharged with some substance but not infrequently it is the presence of the nucleus that leads to the precipitation of the substance that is the nucleus may play either a primary or a secondary role. With a few exceptions the dissolved substance is deposited in a crystalline form, although the crystalline structure may in time partly disappear through condensation or through filling the interstices with some other material. The structure of the concretion depends on two factors. The crystals tend to be deposited at right angles to the surface and thus give a radiating structure

The ease and frequency with which the presence of *escherichia coli* was demonstrated in the bile together with the evidence that cholesterol could be precipitated in vitro from bile inoculated with these bacteria (Gerard 1905 Kramer 1907 de Lavergne and Kiesel 1935 and many others) proved a very seductive and reasonable theory to explain the cause of gallstones.

However several writers, especially Rovsing disputed the validity of this conclusion. Gumprecht (1895) asserted that the normal bile is free from micro-organisms and that the notion that gallstones are formed from symptomless infection of the bile was "nothing but an hypothesis." Chauffard (1922) observed that for some physicians and surgeons the infectious origin of biliary lithiasis is a kind of dogma and concluded that the largest number of gall stones escape an infectious pathogenesis." Lichtwitz (1929) called attention to the fact that severe purulent biliary infections render certain no gall stones will be formed (Schwereltrige Gallenprozesse machen sicher keine Steinbildung).

A similar story could be related about the rise and fall of the theory that *ebertella typhosa* caused gallstones. The former world-wide epidemic of typhoid fever and the frequently proved presence of *ebertella typhosa* in bile and also in gallstones, as well as in the walls of gall bladders of typhoid carriers, served to indict this organism by testimony similar to that used against *escherichia coli*. But when the incidence of typhoid fever greatly declined and the incidence of gall stones remained the same or showed an increase, this explanation of their cause had to be abandoned.

In more recent times, little convincing evidence has been presented to prove the primary importance of the infectious theory although for many writers, the dicta of Naunyn (150) and his school still prevail. In 1924, Schragr suggested that the gall stones of middle life are the end product of a cholecystitis which originated during the first pregnancy. Branch (1929) added to the confusion by asserting that "the organism recovered from a case of acute cholecystitis is not necessarily the primary etiologic factor responsible for the development of the acute lesion. Umber (1932) concluded that the presence of bacteria in the bile (bacteriocolia) did not necessarily mean disease, as the lower part of the biliary tract always contained micro-organisms. He also mentioned that an otherwise harmless organism might become pathogenic. Even as late as 1932 Aschoff (12) apparently was much impressed by the data concerning the association of the enterococcus with

infection of the biliary tract.¹ The accumulated literature on the relation of bacteria to the production of gallstones, as well as to other diseases of the biliary tract, has grown to enormous proportions. Every conceivable aspect has been investigated. The kinds of micro-organisms, their paths of entry into the bile, the nature of the lesion they produce the attempted simulation of these activities by experiments with laboratory animals, and many other phases of the subject have received attention. However clear-cut proof that gallstones are ever primarily caused by infection with bacteria has not yet been offered. Carter and his coworkers (1939) adopted a somewhat cautious view when they wrote, "As the result of many careful pathological, bacteriological and physiological investigations we are coming to the conclusion that infection is the primary cause of disorders of the gallbladder in the minority of cases, and they finally summed up the matter by the following statement. Experiments pertaining to the origin path and effects of infection upon the gallbladder have been conducted by Roseow, Graham, Judd, Mentzer (142) MacNeal and many others without arriving at final conclusions as to the specific role played in gallbladder disease by infectious bacteria.

Summary On the whole there is little evidence in favor of the theory of infection. At the same time both the occurrence and the seriousness of infection of the biliary system by virulent bacteria must be admitted. They may cause profound and often fatal disturbances. Also, micro-organisms, of all degrees of pathogenicity including purely saprophytic types, may and undoubtedly do gain entrance to the bile and are occasionally demonstrable in that medium, in the walls of the gallbladder and even in the gallstones themselves. Theoretically they may, by agglutination, form clumps which act as nuclei for the aggregation of precipitated cholesterol and bile pigments. However, the theory that they play any major role in causing gallstones must be abandoned.

ASSOCIATED DISEASES AND CONSTITUTIONAL SUSCEPTIBILITY

In the efforts to detect some common basis for the formation of biliary calculi, repeated studies have been made of the possible etiological relationship of gallstones to other diseases. The earliest of these was undertaken to prove the simultaneous occurrence of urinary calculi and cholelithi-

¹This organism was named by Tiberius in 1890, and in 1902 was called the "bacteriocolia" by Anderson and Herber. Its chief claim to recognition arose from its apparently frequent presence in the bile (Meyer 1904; Meyer and Lippman, 1905, and Pomeroy, 1911), as well as its resemblance to *escherichia coli* in shape and ability to ferment in bile.

asis. However the number of patients who harbored both types of stones has not proved to be large enough to justify any thought that they had the same cause. For one thing more men than women have urinary calculi, while the reverse is true for gallstones. The relative incidence of other diseases, such as arteriosclerosis, gout, and even fatty changes in the liver and tuberculosis, in cases of gallstones has been reviewed with the same end in view but with not even suggestive results.

The statement that there is an increased incidence of gallstones in cases of diabetes seems to have good statistical support. Isolated instances of diabetes or glycosuria developing after attacks of gallstone colic, often with jaundice have been reported by several early writers. Loeb apparently was the first to report such a case in 1879 and other cases have been reported by Hull (1882) Kraus (1884) Roger (1886) Ord (1887) Sweet (1889), Gans (1891) Gilbert and Well (1898) Weldenbaum (1898) and Kausch (1899). In answer to a discussion of his paper by Gans, Naunyn (190) expressed doubt as to any association of gallstone colic with glycosuria, and in his book (191) published in 1892, he stated 'I cannot confirm from my own experience the frequent appearance of sugar in the urine in connection with gallstone colic. Finally in an article entitled *Diabetes mellitus*, published in Nothnagel's *Encyclopaedia of Medicine* in 1898 Naunyn asserted that in 250 patients with gallstone colic he had not once noted glycosuria except in cases in which the disease was complicated by disease of the liver. Lenné (1898) expressed a similar view. Zinn (1898) held that sugar in the urine of patients with gallbladder disease was a very rare event, and Kausch (1899) concluded 'In gallstone disease (without complicating disease of the liver) glycosuria is very uncommon (*höchst selten*)'. Hochhaus reached a similar conclusion in 1907.

According to von Noorden and Isaac (1927) Bouchard in 1891 was one of the first to report on a series of cases of diabetes. He found gallstones in 10 per cent of his patients with diabetes. Seckel (1925) among 430 cases of diabetes could discover only 26 (6 per cent) patients who had gallstones. Jones and his associates (1925) examined the duodenal contents of 68 diabetic patients and concluded that 15 (22 per cent) of the patients had or had had gallstones. They indicated that 'the existing figure for the incidence of gallstones in diabetics is far too low' and that probably one-fifth of all diabetic patients over forty have an associated cholelithiasis. Wilder in 1926 found that gallstones were present in 16 or 28 per cent, of 58 cases of diabetes in which

postmortem examination was performed at the Mayo Clinic. He believed that disease of the gallbladder is an etiologic factor of importance in diabetes. Woehrmann (1928) found that 160 of 677 diabetic patients had gall-bladder disease and Katsch (1928) reported 'gall-bladder changes' in 14 of his 36 cases of diabetes, an incidence of nearly 39 per cent. Warren (1938) collected data from the records of 453 postmortem examinations of diabetic patients more than thirty years of age. Gallstones were (or had been) present in 140 (31 per cent) whereas in 500 consecutive postmortem examinations of nondiabetic patients of the same age group gallstones were found in only 21 per cent. In 1941 Dry and Tessmer reported that gallstones were present or had been removed by operation in 50 or 27 per cent, of 182 cases of diabetes observed at the Mayo Clinic.

I have reviewed the statistics of postmortem examinations made at the Mayo Clinic during the years 1934 to 1943 inclusive. In 4,761 cases in which such an examination was performed on patients twenty years or more of age sufficient data were recorded regarding the presence or absence of gallstones at the examination or their previous removal by operation. This number 4,761 included 3,016 (63 per cent) men and 1,745 (37 per cent) women. Gallstones were present or had been present in 1,032 cases (22 per cent).¹

Of the 1,032 patients in whom gallstones were or had been present, 500 were men (17 per cent of the 3,016 men examined) and 532 were women (30 per cent of the 1,745 women examined). Diabetes had been diagnosed in 205 of the 4,761 individuals. Of these 205 patients with diabetes 124 were men and 81 women. Of the patients who had diabetes, 76 (37 per cent) had gallstones. Of the men who had diabetes, 41 (33 per cent) had gallstones the corresponding figure for women was 35 (43 per cent). Of the 4,556 patients in whom diabetes was not present and whose bodies were given postmortem examinations, 2,892 were men and 1,664 were women. Of these nondiabetic patients 956 (21 per cent) had gallstones. Of the nondiabetic men 459 (16 per cent) had gallstones the corresponding figure for women was 497 (30 per cent). Thus the presence of diabetes apparently increased the incidence of gallstones in this series by 17 per cent for men by 13 per cent for women and by 16 per cent for both sexes.

Not all authors have agreed that there is any significant relationship between diabetes and cholelithiasis. In 1892 Naunyn (191) stated, 'It is

¹Doehat and I reported the incidence of gallstones at postmortem examinations as 16 per cent in the years 01 to 04, inclusive (1 the Mayo Clinic). We considered all ages, and in many of the earlier records data on gallstones were substantially incomplete.

not permissible to conclude there is a causal relationship seeing that both diseases cholelithiasis and diabetes, are quite common and no special explanation is required of their occasionally attacking the same individual. Strauss (1898) likewise asserted that gallstones never or very rarely are associated with diabetes, and Lenné (1898) agreed that liver diseases and diabetes mellitus do not possess a causal relationship (*Leberleiden und Diabetes mellitus nicht in einem Causalverhaeltnisse stehen*). In 1924, Campbell wrote "There is an equally large amount of cholesterol in the blood in cases of diabetes and some types of nephritis and there is no tendency for gallstones to be associated with these diseases. Fowweather and Colinson (1927) concluded "Increase of blood cholesterol alone does not cause gallstones as it is well known to increase in diabetes but there is no particular relation of diabetes to gallstones. Joslin and his associates (1935) in 1940 noted that Dublin and his colleagues (1934) also were able to demonstrate little or no connection between gall bladder disease and the development of diabetes.

In spite of these and other similar statements it is quite clear and must be admitted that diabetic patients especially women are predisposed to harbor gallstones. Also there seems to be little if any dispute as to which of these two diseases appears first. Joslin and his collaborators (1940) stated that the average age of 189 patients at the time a diagnosis of gallstones was made was forty-seven and seven-tenths years, and in 199 cases of diabetes the average age was fifty-one and three-tenths years. They also quoted Jordan's conclusion that in the average case a diagnosis of gallstones was made twelve and nine-tenths years prior to the onset of diabetes. As to etiological sequence, I have been unable to find a single author who supported the possibility that diabetes favors the formation of gallstones. On the contrary many have contended that patients with gallstones are particularly liable to have diabetes and thereby have inferred that gallstones might cause diabetes. Joslin (1927) suggested that "the gallstone variety" of diabetes was the most favorable type of this disease and that it frequently could be improved or if the diabetes had not yet occurred it could be prevented by the removal of the gallstones. Jones, McKittrick, and Root (1925) Geddes (1926) and McKittrick and Root (1928) agreed¹

Whether the same factors that produce gallstones also may cause diabetes or whether it is only the complications of gallstones, such as infection or injury to the liver that are effective, are matters for further investigation. In either instance the study of the relationship between these two diseases does not appear to furnish any demonstrable clue as to why gallstones are formed.

Frequently final conclusions as to the cause of cholelithiasis have been expressed by such vague terms as disordered metabolism or "metabolic disturbances." These and similar phrases, which are comprehensive and indefinite are often the last resort of the befuddled investigator. Occasionally more exact terminology is employed, as, for example, faulty metabolism of cholesterol, bile pigments or calcium, and hypercholesteremia. But the most commonly used and least frequently interpreted disturbance of metabolism is conveyed by the word obesity. The alliterative phrase, "fair fat and forty"² has become a sort of shorthand among clinicians as a description of those most likely to have gallstone disease. Strangely enough the association of obesity and gallstones has been the subject of very few definite investigations.

In an analysis of 255 patients with gallstones Zellweger in 1913 found that 87 (34 per cent) were well nourished and 14 (5 per cent) were obese. Mentzer (1926) indicated that the percentage incidence of gallstones increased materially with the increase in overweight.

In 1929 Gross reported that the average weight of 143 men with gallstones was 131.65 pounds, and that of 174 women with gallstones was 126.07 pounds, while the average weight of 500 men without gallstones was 119.24 pounds and that of 500 women without gallstones was 103.35 pounds. In an analysis of insurance statistics, Dublin and his colleagues (1934) stated "The susceptibility of fat women to gallbladder disease is evidenced by the high proportion of women, nearly eighty per cent, in this group. They estimated that in their series, 51.8 per cent of the women were at least 5 per cent, and that 22.8 per cent were 15 per cent, above normal average weight. In their book "Diagnosis and Management of Diseases of the Biliary Tract," published in 1939, Carter and his collaborators gave the summary of a sequence suggested by many investigators of gallstones during the past one hundred or more years. In a discussion of the hypotonic gallbladder they stated

Sedentary habits obesity deficient muscular

¹This phrase has been ascribed to Deaver (22) and he actually used it in a paper published in 1920. It was probably employed earlier and perhaps by other authors.

²In justice to Joslin and his colleagues (1935), it is only fair to quote the following quotation from their book: "The treatment of diabetes mellitus, published in 1935. In view of the present emphasis of the common hereditary basis of diabetes we believe that one can no longer ascribe to gallbladder disease primary etiologic role. It seems fair to conclude that although gallstones and cholecystitis occur more frequently in diabetes than in non-diabetics, gallbladder disease cannot be regarded as primary factor in the causation of diabetes.

tone, and low metabolic rates are common in both sexes having this type of dysfunction. Most of the patients belong to the fair fat and forty' group. Joslin and his coworkers (1940) who have emphasized the role of obesity in diabetes stated that they were inclined to agree with Terbruggen (1937) who asserted that the occurrence of gall-bladder disease in a diabetic patient is explained by the obesity which is commonly present in such a person.

In an analysis of the 1032 instances of gallstones previously mentioned (page 7) I found that 578 (56 per cent) of these occurred in individuals estimated to be of normal or subnormal weight. The remaining 454 (44 per cent) were judged to be above normal weight. In the first group (578) there were 333 (58 per cent) males and 245 (42 per cent) females. In the group above normal weight (454) there were 167 (37 per cent) males and 287 (63 per cent) females. These estimations admittedly are not exact. Indeed most figures on obesity can only be approximate. However these figures tend to confirm the opinions of other authors namely that women at least, who have gallstones are inclined to be overweight at the time of their death.

In spite of these figures and the opinions just cited no one has been found who has contended that obesity was a *sine qua non* for the production of gallstones. Bettman and Tannenbaum in a study of gall-bladder disease published in 1944, said, "We purposely chose this woman of thirty-five years of age with black hair and loss of weight to emphasize the fact that the well-known line about fair fat and forty' should not mislead us. Also it must never be forgotten that the gallstone carrier most probably becomes a patient a considerable time after the calculi have formed. More careful study is indicated to determine whether obesity is really one of the factors in the production of gallstones, how obesity influences this production and whether the presence of gallstones tends to promote obesity and even perhaps the sedentary life commonly ascribed to patients, especially women, with gallstones."

Any discussion of obesity and its relation to gallstones naturally introduces the problem of individual and class, or group susceptibility to one or both conditions. Almost from the time that theories about the cause of gallstones began to appear it has been the assumption of many authors that gallstones represent the results of an abnormal constitutional make-up. As Dieulafoy (48) (quoted by Chauffard, 1922) expressed it "L'état diathésique domine le pathogène de la lithiasis biliaire (the diathetic state dominates the patho-

genesis of biliary lithiasis). Other equally vague terms have been employed, such as cholesterol diathesis, constitutional factor 'familial tendency', 'predisposition', "pregnancy cholesterol diathesis", "racial differences," and so forth. Bowen and his associates (1928) were no more specific when they stated that the frequent association of diabetes obesity and gallstones was probably a matter of constitution."

This is not the place to review the literature which has been collected about the relation of constitution to disease.² Attention must be confined to a few pertinent references to the relationship between the production of gallstones and specific body types. One of the earlier authors to hint at this association was Beneke (16) who in 1876 found that of 30 persons with gallstones 19 (63 per cent) had "Eine starke Fettbildung" (a marked corpulence).³ Zellweger (1913) said she had observed an heredity in cholelithiasis in the form of whole gallstone families. Just as in many obscure causes of disease also in cholelithiasis, disposition and constitution play a role. She quoted Bartel, who made the first important studies on this phase of the etiology of gallstones and said "As to the tendency to concretion formation in the front rank is cholelithiasis which frequently discloses an abnormal constitutional predisposition. In 1916 Bartel wrote a paper on "Cholelithiasis und Körperkonstitution" in which he again concluded "In calculus formation, especially in cholelithiasis abnormal constitutional conditions of the entire organism are present. He recommended that in every case in which gallstones are discovered at postmortem examination the constitutional characteristics of the individual should be carefully investigated."

In this country Draper has contributed numerous studies of the relation of physical conformation to specific conditions, especially duodenal ulcer and diseases of the gall bladder. His latest book (49) published with the collaboration of Dupertuis and Caughey, in 1944 is entitled "Human constitution in clinical medicine. These

²In the second edition of Dieulafoy's "A text-book of medicine" (47) translated by Collins and Liebsmann and published in 1912, the following sentence appears: "My ideas agree absolutely with those expressed by Huxley—that the diathesis is a factor in the pathogenesis of lithiasis." Dieulafoy also summarized the theory which then prevailed in France when he stated, "Biliary lithiasis is often associated with the diathetic conditions that form part of the group of arthritic diseases—rheumatism or rheumatism, urinary lithiasis, obesity, asthma, diabetes and eczema." The word "arthritic" is used in the sense of the French word "arthritisme" (arthritic diathesis) which was employed by the writers of Dieulafoy's time with broad and special significances.

³The subject has its own journal (Zeitschrift fuer Leber- und Gallenkrankheiten) and references to it have reached astronomical proportions. Tucker and Lewis in 1920 estimated that, in the previous five years, fully 7000 titles had been listed.

⁴According to Fegeshbaum and Howitz (154) Brodie (17) in his book entitled "Die Atterdisposition," published in 1870, was the first to report measurements of the body in support of his theory.

authors reported studies on 90 patients with diseases of the gall bladder. After noting that "women are more prone to gallstones than men in the proportion of five or six to one, and recalling the old medical saying that the commonest type of woman to be affected is fair fat and forty" they concluded from numerous physical measurements and observations that, when gallstones occur in man there is a "strong emphasis on gynecic characters in his total person. These included 'gynecic contour, fat distribution, gesture, facial expression and turn of mind.' Men of gallbladder type possess wide heads, moderately short and broad faces. Roundness and softness characterize the otherwise regular features of the face and their hips are somewhat broad and the trunk is rather short. The massiveness of the gallbladder physique is more clearly shown by the very broad and deep chests which exhibit the largest circumference found in any male group. Similarly these authors asserted that 'women with gallbladder disease are in general of a soft, round or lateral type of build. These women the authors claimed, have 'fairly broad shoulders and the broadest hips of any female disease group. Their chests are by far the broadest and deepest and the chest circumference-stature ratio is the largest recorded in the study."

Disagreement is usual with every theory about the pathogenesis of gallstones (or any other disease for that matter) and some authors do not admit the influence of constitutional tendencies in this disease. Chauffard in a masterly book on biliary lithiasis, published in 1922 rather naively concluded that, on the whole, heredity played no important role, but in men in whom hypercholesteremia (which was observed by him in women during pregnancy) was not present "heredity is more important." Feigenbaum and Howat (1934) reported as follows "Our results do not bear out Draper's conclusions. In 1935 they asserted "The conception that the physical constitution of a person is an important factor in the etiology of disease arose from the observations of the effects of certain diseases on the body. At no time were these effects controlled in investigating the subject. Thus a clinical impression which is erroneous, viz. that the anatomical habitus is one of the causes of disease, was perpetuated." Tucker and Leasa in a lengthy review entitled 'Man a constitutional investigation' (1940) commented as follows "Draper presents a mass of statistical data which is exceedingly hard to evaluate."

Finally Julius Bauer the dean of modern writers on constitution and disease in 1912 wrote as follows in reference to Draper's theory: "The etiology and pathogenesis of most diseases are too complicated to conform to so simple a concept as that mentioned. One can hardly expect an ulcer or gallbladder type of human habitus. What may be and has actually been found however is a greater frequency of various diseases in persons exhibiting a particular habitus. Habitus is never the cause of a disease. It may be an indicator of a morbid disposition. Thus one must leave this fascinating question. I have an idea that the last word along these lines has not yet been written, but concerning the theory that constitutional factors play any effective part in the primary pathogenesis of gallstones, there seems to be considerable doubt."

Summary The attempts to associate in causal relationship any other disease and cholelithiasis have proved uniformly unsuccessful. Apparently more diabetic patients have gallstones than do nondiabetic patients and there must be some, as yet hidden explanation for this fact. Almost all investigators are agreed that diabetes, when it occurs, follows the presence of gallstones, but none has proposed that diabetes causes them to form or that the two diseases have a common cause.

In regard to obesity and gallstones, the inquirer finds much confusion in attempts to correlate the two conditions. Most of this arises from the uncertainty as to the actual time at which biliary calculi begin to form. It is the status of the individual *before* this time and not afterward that is pertinent, and for this period of life there is naturally little or no information obtainable. The problem of overweight is closely linked with the effect, if any, of heredity and constitutional tendencies. Here also it is difficult to trace any simple or understandable relationship. The proponents of specific constitutional patterns for given diseases have not produced, and perhaps are not concerned with etiological data. However they have gathered together an imposing array of scientific collaborators and have presented so many facts that their claims cannot be ignored. It seems eminently reasonable that certain types of individuals who possess, largely by inheritance, similar physical structures and mental traits should thereby be subject to similar pathological conditions. Mental hospitals are filled with examples of this tendency. The physically awkward and careless thinking person is a poor risk for accident insurance. But even if the individuals who are going to acquire gallstones could be selected on the basis of their build and disposition, at present one is no nearer

Dubin and others (1931) reported that Draper "went so far as to say that he could go down the side of a corpse in hospital and pick his gallstone cases."

to a solution of why they or the many others who do not conform to this type have gallstones

NEUROGENIC DYSFUNCTION

In all the welter of theories and etiological data, it was inevitable that neurogenic phases should receive consideration. In the early part of the eighteenth century Hoffmann (1731) according to Luetkens stated that the nerve anastomoses between the stomach and duodenum on the one hand and the bile ducts on the other could lead to 'irritative Irradationen'. In the more than two hundred years since then similar concepts frequently have been expressed. The possible association of duodenal ulcer or even disease of the appendix with gallstones has been thoroughly explored. In 1930 Birch and Boyden suggested that the dysfunction and stasis of the gallbladder [with the consequent formation of gallstones] may be due in part to inhibitory reflexes arising from chronically diseased portions of the gastrointestinal tract.

The temptation to review all the stages in the development of the so-called neurogenic theory must be resisted. It should suffice here to note that, preceded by the ideas of John Berg among others, and encouraged by his chief von Bergmann Karl Westphal in 1922 published a 'mile stone' paper entitled 'Relation between the pathology of the biliary tract and the vegetative nervous system'. Other communications by Westphal followed on various phases of physiological, especially neurogenic, as well as pathological and clinical manifestations of the activities of the biliary system. In 1931 Westphal and his colleagues (219) published a book entitled 'Gallenwegsfunktion und Gallensteinleiden' (Biliary tract function and gallstone disease). In the following year (218) Westphal brought out a review of his previous ten years work on 'The motility and absorption disturbances of the bile ducts and their complications'. He noted that since the report of Nauyn (151) stasis in the biliary tract had been regarded as a prerequisite for the production of gallstones and that he (Westphal) had demonstrated that this stasis was the result of a 'dyskinesie' of the musculature of the extrahepatic biliary system. As proof of his theory he referred to the results of previous experiments on rabbits, in which by means of a weak irritation of the vagus, he claimed to have noted an increase in the motility of the smooth muscles of the gall bladder and bile ducts, with consequent contraction of the gall bladder and expulsion of bile into

the duodenum. If the stimulation of the vagus was stronger there resulted a spastic contraction of the ring muscle of the papilla of Vater together with increased tonicity and contraction of the muscle of the gall bladder. But the flow of bile into the intestine was prevented by the spasm at the entrance of the duct into the duodenum. This effect he denominated 'hypertonic biliary stasis.' The opposite of this was caused by stimulation of the splanchnic or sympathetic nerves, which caused relaxation of the musculature of the biliary tract with passive dilatation of the gall bladder a 'hypotonic biliary stasis'. Westphal concluded from these and other observations that overstimulation or oversensitivity with resulting abnormally strong responses of either the sympathetic or vagus (parasympathetic) nerves produces a pathological disturbance in the physiology of the biliary system and prevents the prompt discharge of bile and thus tends to favor infection gallstone formation bile-duct colic and other clinical manifestations. He called the nervous dysfunctional state a cholangiopathy and asserted that it occurred more frequently in women because they were more liable to hypophyseal or gonadal hormonal disturbances, particularly at menstrual periods or because of pregnancy. He affirmed that in pregnancy the evidence of a hypertonic gall bladder stasis with slowing of the emptying time, which had been demonstrated by pharmacologic experiments was positively confirmed by the use of special dyes and roentgen rays. He interpreted these phenomena as signifying an increased sensitivity of the parasympathetic nervous system in pregnancy.

Inhibition of the function of the gall bladder during pregnancy was first demonstrated in animals by Mann and Higgins in 1927. Potter examined the gall bladders during 390 cesarean sections on women at full term. In 75 per cent of these women he found a large distended gall bladder which he interpreted as the result of stasis from some "metabolic dysfunction associated with functional motor disturbance rather than infection or mechanical pressure. Similarly Gerdes and Boyden concluded that there was in pregnant women a hypertonic condition of the common duct sphincter due to a physiologic dyskinesia reflecting the changed hormonal content of the organism in pregnancy. They thought that the stasis of pregnancy sets the stage for the sequence of events which results in the greater incidence of gall stones among women who have borne child.

Earlier 'distensions' in the study of cholelithiasis might be selected as follows: Ferrel (354), Farncombe-Dufresne (185), Merkel von Harnbach (189), Nauyn (189) and Aucher and Barthelemy (190).

Schmiedeknecht and Neuen (1933) called this "cholepathia spastica". Newman (1933), "spastic distention"; Ivy and Sawaburo (1931), "biliary dyskinesia". Lyle Bert and Hicken (1931) used the term "biliary dysmyotonia".

dren From cholecystographic studies many workers reached similar conclusions although there were a few who obtained contradictory results.

Summary. The enthusiasm which has greeted the theories of Westphal and his successors is almost as contagious and far reaching as that which earlier followed the proposal of the infectious theory by Naunyn and his school. It is quite possible that this enthusiasm has led to unjustifiable and too sweeping conclusions, but the mass of evidence that has been collected and the number of previously unexplained phenomena which have now become reasonably and clearly elucidated warrants the expectation that in neurogenic disturbances lies the clue to some of the conditions which govern the formation of gallstones. The transfer of a consideration of purely anatomic changes to a study of purely functional disabilities is a distinct step in advancement of knowledge concerning many diseases including cholelithiasis.

Many other suggestions have been offered to explain the formation of gallstones, chiefly involving minor modifications of the five cardinal theories just discussed but none has received any general acceptance and the defeatist conclusion often has been expressed that multiple and frequently variable factors including some that are still unknown unite to produce gallstones. Thus there has resulted an impasse of sorts on the etiology of gallstones, and many writers have unwittingly agreed with Johannis Schenkii (reference from Chiray and Pavel, 1936) who in 1644 wrote that gallstones, acting secretly make us to be ignorant of the cause. "After a lapse of more than two hundred and fifty years, Rambert in 1899 agreed that 'the pathogenesis [of gallstones] is not clearly known,' and Levyn was equally discouraging when in writing about the gall bladder he said "Even today [1932] there is much about that simple organ that is baffling." Bacmeister was quoted by Kehr (1923) as having concluded "The gallstone is a symptom of a condition in which the diseased picture is not fully revealed nor the special cause of the illness encountered." Salkowski (1922) rather sarcastically remarked that he could not understand why the question of the formation of gallstones produced so much "Kopfschmerz" (headache) among pathologists and clinicians as he was convinced that too much cholesterol or too little bile acids certainly caused the precipitation of the solids of gallstones. Nevertheless he found the problem of why this change occurred a "nicht so leicht zu lösende Frage" (a question not so easy to solve). Roux and others (1919) pessimistically asserted in 1924 "The literature [on the formation of gallstones] has been from early times too heavy

with hypothesis and dismal with uncorrelated observations. A similar conclusion was expressed by Sobotka in 1937 when he said "The formation of gallstones, the role of bile in the emulsification and resorption of fat, the emptying mechanism of the gallbladder are topics, where the extensiveness of the literature is more imposing than its depth and where abundance rather than scarcity of detail detracts from the clarity of the evidence available." After a very complete review of the subject, Laetkens (1936) admitted that although the supposition of Westphal namely that primary stasis of bile is the consequence of motility nervous of the biliary tract, had been confirmed, "the last word has not yet been said on the colloid chemistry or the sources and conditions of gallstone precipitation. Peel (1927) was certain that changes resulting from inflammation of the gall bladder were not fully understood while Sweet (1927) was convinced that "the problem of the formation of gallstones is not a problem merely of infection or of bile stasis, but one involving the metabolism of cholesterol, concerning which we as yet know nothing." In 1929, Lichtwitz (1926) in a paper on the "Principles of concretum formation" asserted that the preponderance of gallstones in women over those in men depends upon drastic anatomic and functional differences between the two sexes, but that it could also arise from some other and unknown cause. He added that although the theories of Berg and Westphal were of great significance there was no proof that they were any explanation for the occurrence of gallstones. "One must conclude," he said, "that the real factor is not known. It may be functional. Nuboer (1931) studied the extrahepatic biliary system and reported "In spite of numerous important researches, the results are inconsequential and as yet only a few definite facts are known on the contrary there are innumerable theories which in general differ widely from each other.

Weiser and Gray (1934) concluded "The precipitation of cholesterin in the gallbladder is altogether inadequate to account for the formation of pure cholesterol concretions." Phemister, Aronson and Peplinsky (1939) asserted that "the fundamental cause of gallstones is very little understood and, finally, Walters and Snell in their book "Diseases of the Gallbladder and Bile ducts" (1940) wrote, "Neither infection stasis nor metabolic disturbances furnish a completely satisfactory explanation of the development of cholecytic disease in general.

In spite of these pessimistic conclusions and in spite of the extremely confusing and often dan-

metrically opposed theories and conflicting results of experiments and observations by scientists during more than four hundred years, several indisputable facts have emerged.

The first and, unquestionably, the most important of these facts is that while gallstones are found in both men and women they occur more frequently in women. It should be emphasized however that, although there is practically universal agreement concerning the preponderance of gallstones in women, this preponderance is not nearly as great as many earlier authors had believed.

In the attempt to explain this well authenticated difference in the incidence of gallstones in men and women, it was to be expected that the functional processes peculiar to women should be closely scrutinized. Therefore, when Schroeder a pupil of Naunyn's in 1892 announced that of 110 women in whom gallstones were found at post mortem examination 99 or 90 per cent, had borne children the problem seemed to have been solved. Most subsequent writers agreed with Naunyn that pregnancy and pregnancy alone accounted for the increased incidence of gallstones in women and there were published numerous statistical surveys which apparently fully supported this contention. In the study by Dochat and me referred to previously there were recorded figures from the reports of 26 authors which showed that of 14,016 women with gallstones, 11,154 (80 per cent) had been mothers. Of 1,413 women who were proved at postmortem examination at the Mayo Clinic to have had gallstones, 1,185 (84 per cent) had had one or more children. Thus the decisive influence of pregnancy as a factor in the formation of gallstones would appear to have been abundantly demonstrated.

But a few writers, notably Branon Scheel Hansen Molnar Hurst, Lichtwitz (124) Gross, and Blumel challenged the validity of this conclusion and Dochat and I made an extensive review of the matter. It was quite evident to us that, as Hurst, among others, had emphasized many authors had completely disregarded the fact that about 80 per cent of all adult women have borne children; therefore, any analysis of the number of adult women with gallstones (or with many other diseases for that matter) would reveal that about 80 per cent of these women also had passed through one or more pregnancies. Thus the view that pregnancy alone accounts for the relatively increased frequency of gallstones in women is largely invalidated. The word, 'largely,' is used advisedly. Although there can be little doubt that pregnancy does not wholly explain why more

women than men have gallstones there is still evidence that pregnancy among other factors may exert some influence in producing this disease. The slight discrepancy noted by several authors, between the percentage of women who have had children and the percentage of those women who have gallstones would tend to support this suspicion.¹

As would also be expected other phases of women's sex functions have received deserved attention. For example Chauffard in 1922 noted a publication by G. P. Gonalous in Buenos Aires in 1916 in which there was demonstrated an increase of cholesterol in the blood of women at each menstrual period. From this and other work, Chauffard concluded that 'during her entire sex life a woman has repeated increases of cholesterol in the blood and this accounts for her predisposition to gallstones.' Okey and Stewart and according to Carter and his colleagues (1939), also Leuret and Dutrent found hypercholesteremia associated with the menstrual periods. Eckelt (1917) called attention to the work of Heilig (1924) who found signs of functional disturbances of the liver during menstruation. Eckelt argued that during the menses the vegetative nervous system is in a state of increased excitability and agreed with Westphal concerning a 'vagotonic motility nervous of the gallbladder' in the menstrual period. Chiray and Pavel (1936) stated that biliary lithiasis is often due to an endocrine dysfunction and directed attention to the irregularity of the menses in such patients.

The disturbances which often accompany or follow the menopause in women have occasionally been cited as factors in causing gallstones but evidence for this view is entirely lacking. That so-called gallstone attacks may and do occur at this period of a woman's life and even that this cessation of function may in some unknown manner favor these attacks cannot be successfully denied. But gallstone attacks must not be mistaken for signs that gallstones are formed at these times.

The last sentence naturally introduces the second fact about gallstones one which in all its phases has certainly not received the attention it

¹The difficulty of determining, by statistical compilation, just how effectively the influence of pregnancy operates arises from the fact that accurate estimation of the percentage of women who have borne pregnant is hedged about by numerous obstacles. Secret abortions and miscarriages, particularly among single women, as well as the concealment of normal childbearing, vitiate the results of any inquiry into the relative frequency of pregnancy. Conversely the exact percentage of women who have had gallstones rarely can be accurately determined. A survey of a large number of cases is necessary and each survey is subject to errors of interpretation or imperfect observation. Also, gallstones may have passed into the intestines through the bile ducts or through spontaneously developed fistulas, and their former presence thus escape detection.

deserves. Reference is made to the logical conclusion that gallstones in both men and women are formed almost exclusively during the active sex life of the individual. They are very rarely found in children and probably they appear only several years after puberty. Deaver and Ashhurst (44) said: "It is our belief based upon clinical experience, that most gallstones are formed between the ages of twenty and forty."

The proof that the production of gallstones ceases at or near the menopause is not so easy to verify. The widespread fallacy of confusing the symptoms of gallstones with the time of their formation especially in statistical summaries complicates the problem. It is unfortunate that much of the data about gallstone disease consists of references to "gallstone attacks," meaning either frank colic or more or less serious digestive disturbances. It is highly probable that the signs and symptoms of the presence of gallstones have absolutely nothing to do with the causes of their production. Therefore when it is argued that the menopause or a sedentary type of living or even obesity is conducive to the formation of gallstones the supporting facts which are cited often refer to clinical phenomena caused by the calculi, when as a matter of fact the gallstones themselves may have been present for many years without producing any recognizable signs. Carter and his co-workers (1939) clearly recognized this when they stated that their study [of 100 postoperative cases of gallstones] serves to emphasize the difficulty of determining the cause and pathogenesis of gallstones solely by study of the patient at the time of operation. The period of calculus formation may be limited and a study of the patient one to twenty five years later will fail to present the true picture of the condition determining the deposition of the stone." Whether gallstones are ever completely without signs or symptoms is largely an academic question. The fact remains that a relatively large number of individuals harbor gallstones which escape the notice of patients, relatives and attending physicians, and are discovered more or less accidentally at operation or at postmortem examination.

The comparatively narrow limits of time in which gallstones are usually produced in men and women were emphasized by Aschoff (11) when he wrote in 1931, "Cholesterol stones are formed during a relatively short period of life. Although it is possible that occasionally secondary formation of gallstones, particularly in badly diseased gall bladders may take place in the later decades of life there can be little doubt that the primary production of these calculi is confined to the third

fourth, and possibly fifth decades of life, that is, during the periods of sexual activity."

The third fact, closely related to the second, has likewise been largely neglected by most writers. In 1846 Hein noted that Sommering in his "*De Concrementis biliaria corporis humani*," published in 1795 asserted "Gallstones come 'auf einmal' [all at once] and not one after the other." In 1921 Knox expressed the same opinion when he wrote that gallstones are "usually in one crop" and the time of formation is relatively short. In the same year Roux and others stated, "The frequent presence in human gall bladders of large numbers of calculi of practically identical size and character has led to the general recognition of the importance in such instances of critical periods of stone inception and formation." Lichtman, in his book "*Diseases of the Liver Gallbladder and Bile Ducts*," published in 1942 also wrote about "fitters of gall stones" which might be formed in a short time as two months. In effect, this fact is based upon the well founded assumption that, whatever influences operate to produce gallstones, they are not constantly active in effective degree, and that gallstones are usually the result of a transient episode, which while it admittedly may be repeated, is not continuously in operation and is not of any marked frequency periodic or otherwise.

The fourth fact to which I wish to draw attention cannot be, and has never been, disputed by anyone but should be continually emphasized. This is that while the causes of gallstones, it is clear, act more effectively in women than in men, nevertheless, almost as many men as women have gallstones. In other words, whatever factors produce them in women the same factors operate with almost equal effectiveness in men. Here also the available evidence is wholly in favor of the view that in men as in women, gallstones originate during the period of sexual activity. Also, in this connection it may be particularly significant that several writers have presented data which imply that gallstones are produced in men, on the average at a later period of life (five to ten years) than in women. The data upon which this view is based are not conclusive, although highly suggestive. The conclusion depends largely on the fairly well established observation that gallstones are discovered at later ages among men than among

Exceptions to this generalization have been frequently noted. Gall stones have occasionally occurred in children (Kastner, 1911), and also, sporadically, gallstones have occurred in later years, after they are removed from the gall bladder by cholecystectomy. These exceptions do not, however, invalidate the fundamental theory of gallstone formation. Presumably variations or marked prolongation of the latent period is not known. Extensive study of such exceptions may lead to more valuable conclusions than the study of the routine or usual cases.

women. That is the peak of so-called incidence occurs almost one decade later in men. Dreyfus-Brissac (1883) noted that in women gallstones tended to occur between the ages of seventeen and forty two years, while in men the high point of incidence was between fifty and sixty. Scheel (1911) found at postmortem examinations that the same relative number of men and women had gallstones, only the men were twenty years older. Schmid (193) agreed with Dreyfus-Brissac and Scheel that gallstones occur earlier in women than in men—that is, between the twentieth and fortieth years. Aschoff (11) in one of his last papers (1931) referred to Lotm (1926) who demonstrated that the high point of the curve of gallstone incidence appeared earlier in women and reached its peak in the climacterium while in men this peak appeared between the ages of sixty and seventy years. Dublin and others (1934) reported from an analysis of insurance statistics, that gallbladder disturbances occurred in women at an earlier age than in men. For example 20.8 per cent of the affected women were under thirty years of age and 62.6 per cent were under forty years, while among the men with such disturbances the percentages for the corresponding ages were 13.1 and 47.3 respectively. Apropos of this theory is the fact that sexual maturity is usually reached at a later age in men than in women and also that it continues often many years, beyond the period of life when the menopause occurs in women.

The fifth fact, namely, that typical gallstones are formed almost exclusively in the gall bladder hardly needs any argument in its support. As Fowweather and Collinson (1927) expressed it, "Any inquiry into the cause of gallstone formation must be directed against the gallbladder itself." Surgeons and pathologists frequently find true biliary calculi in the common bile and hepatic bile ducts, and some of the surgeons are quite convinced that, at times, the calculi must originate in the bile ducts, because among other reasons when they are discovered they are too large to have passed through the apparently undilated cystic duct. Also occasionally when a considerable interval has elapsed after cholecystectomy and a thorough exploration of the bile ducts stones in the common bile duct have necessitated another operation or have been discovered at postmortem examination. Lahey in 1938 presented very convincing arguments in favor of this theory. How ever Phenister Aronsahn, and Peplinsky (1939) expressed the prevailing opinion when they stated, "Stones in a duct rarely if ever occur in the absence of cholelithiasis. My own personal experience confirms this opinion namely that

practically every gallstone found in the common bile duct or hepatic ducts could more rationally be ascribed to have originated in the gall bladder than in the bile ducts. The tendency of stones loose in the common bile duct to travel upward into the hepatic ducts or to be so completely imbedded in an apullalike dilatation of the distal portion of the common bile duct as to escape discovery is well recognized. The rare instances in which these two possibilities can be excluded should receive careful verification especially cases in which the gall bladder does not contain and in all likelihood never did contain calculi. The passage through the cystic duct of comparatively large stones without a residual permanent dilatation of that duct, and the possibility that tiny stones migrating from the gall bladder to the common bile duct later become enlarged by further deposits must be granted. Finally the character of the suspected primary stones in the common bile duct should be determined in order to be certain they correspond to the type of true gallstones and not to that of simple calcareous concretions which, at times, may be formed in any of the many different channels of the body.

Especially pertinent is the sixth fact namely that gallstones particularly those of the pure cholesterol type may be found in gall bladders, the walls of which are free from any demonstrable anatomic evidence of disease. Aschoff was the first to emphasize this point and many others have admitted or confirmed his conclusions. This fact is the best explanation for the occurrence of silent gallstones and any rational theory of the production of gallstones must be in harmony with this fundamental observation. Furthermore this fact is a direct refutation of the widely prevalent conception that bacterial infection is at the foundation of gallstone formation.

The argument that the infectious episode which caused gallstones might be transient and of such a benign character that there would be no residual anatomic traces was first expressed by Naunyn (151) in his original monograph *Klinik der Cholelithiasis* published in 1892 and was reiterated by him in subsequent papers. The theory became a real boon to certain clinicians and surgeons, notably Fraenkel (1918) Poppert (1921) Umber (1923) and others who found in it a convenient explanation for the occurrence of gallstones in normal gall bladders as well as an explanation for the presence of symptoms of gall-bladder disease such as colic, digestive disturbances, and jaundice in cases in which no stones were found at operation. These symptoms, together with the identification of bacteria especially the *escherichia coli*

in the normal bile were judged to be sufficient evidence in support of their conclusions and often justified for them, the removal of normal gall bladders. The advent of more logical explanations for both of these conditions, such as neurogenic dysfunction and the colloid theories of gallstone formation, has largely replaced the earlier notion of an infectious foundation for many diseases of the biliary tract. This theory aside from the fact that any theory which presupposes a bacterial infection profound enough to cause gallstones or to cause signs and symptoms of cholelithiasis when stones are not present and still produce no permanent alteration in the anatomic structures, is so contrary to all modern conceptions of infection and its results that only an insufficient knowledge of these conditions could excuse such faulty reasoning. This chapter in the development of knowledge of the pathogenesis of gallstones is an interesting example of the many devious trails which must be followed before well established truths come to light.

The importance of the exclusion of pathogenic micro-organisms from the list of primary factors in the etiology of cholelithiasis may not be fully realized. The subject has already been discussed (pages 7 and 8 of this article) but a few further comments seem to be justified. The huge volume of literature which deals with the presumed causal relation of bacteria to the production of gallstones is indeed imposing. It might be roughly divided into two phases. The first was the acquired urge to explain all pathological conditions by the premise of a primary infection with pathogenic bacteria. This tendency was and to some extent, still is a kind of obsession or "idée fixe." The second phase began with the admission that many diseases, including biliary lithiasis were primarily due to disorders which might conveniently be classified under the headings "metabolic" or "neurogenic." With such disorders, bacteria could only play a secondary or minor role. This distinction deserves emphasis. Clinicians, including surgeons, are naturally concerned with all the signs and symptoms of a diseased biliary system. Many of these manifestations, admittedly are due to infection of the bile passages by bacteria. Often such infections occur as complications to the presence of gallstones, especially after the calculi have interfered with the normal function of the gall bladder and bile ducts. Not only may infection of these structures by virulent micro-organisms occur in the absence of gallstones but also it has become increasingly evident in the last decade that functional derangements of the biliary tract can produce serious clinical phenomena, such as

pain colic, and even icterus, again without gallstones being held accountable. Even when the roentgen rays demonstrated gallstones, many keen clinicians were forced to realize that removal of the gall bladder (with the stones) did not always cure the fundamental condition.

Thus the frequent practice of writing about "cholecystic disease" as if there was only one entity with a common cause should be discouraged. As has been previously emphasized the production of gallstones in the anatomically normal gall bladder is largely a subclinical process and the consideration of their cause should be definitely separated from discussions of the causes and effects of the complications which may arise, often many years later from the presence of these stones.¹

Finally one more fact, the seventh, may or may not prove to be pertinent. I refer to the well known tendency for many gallstones to be spherical in shape. It is a common experience to find numerous small stones occasionally several thousands, all about the same size and composed of the same relative constituents and all remarkably round. Not only is the "epioid" character of this occurrence clearly manifest, but also some explanation is desirable to account for their almost perfect roundness. It is true that there is much evidence of the molding of gallstones both by the wall of the gall bladder and by contact with each other this latter influence being used to explain the frequent polyhedral shapes of the stones. But the spheres cannot be wholly accounted for by molding any more than can the many other round concretions in other parts of the body. Collections of such biliary calculi are never formed in a gall bladder closed by obstruction to the entrance of fresh bile and the supposition that colloidal phenomena of precipitation and aggregation are involved must receive serious consideration. Here also it is almost impossible to conceive how the presence of bacteria can play any role whatsoever.

SUMMARY

The principal data and theories embodied in the five important factors advanced in the past to explain the formation of gallstones have now been explored in some detail. Also seven more or less fundamental facts about gallstones and their occurrence have been presented. Some dead wood, such as stasis, infection irritative catarrhal cholangitis, and significant association with any other disease has been cleared away. Furthermore, as

Even more necessary is the effort to distinguish sharply the effects of gallstones and of other biliary disturbances from the mechanical obstruction of the biliary system, which occasionally lead to serious symptoms and discouraging attempts to effect relief.

reptance of the seven fairly well established facts about gallstones considerably narrows the field in which the ultimate etiologic determinants must operate. Any theory which adequately accounts for cholelithiasis must conform to these limitations and must also include and harmonize the remainder of the pertinent data which have been collected about this subject during the past several centuries.

Such a theory must explain why gallstones occur in both men and women, but more frequently and at an earlier age in the latter than in the former why they are formed almost exclusively during that period of life when sex functions are active why they are primarily almost without exception formed in the gall bladder and without any demonstrable anatomic changes in the wall of the gall bladder why they are produced during periods comparatively short in duration occasionally in showers or "litters" never continuously and which periods are rarely repeated and finally why gallstones tend to be rounded when not subject to molding influences by the wall of the gall bladder or by apposition to each other

With these conditions in mind, the conclusion becomes almost inescapable that gallstones occur only when there is a profound disturbance of biliary physiology induced by pathological deviations of hormonally controlled functions. Also in all probability the hormones which are concerned in this dysfunctional attack are those commonly designated as sex hormones, although any or all of the other hormones may be involved.¹

In order to produce gallstones this functional disturbance must result in, at least, two primary changes in the normal physiology of the gall bladder. One is an alteration in the composition of the bile. Theoretically this alteration might occur as a result of an abnormal secretory function of the liver cells. The characteristics of the bile are often profoundly affected by pathological changes in the hepatic parenchyma, but there is little evidence to connect these with cholelithiasis. As previously emphasized the changes in the constituents of the bile which lead to the formation of gallstones occur primarily in the gall bladder. So far as is now known, the most important of these changes is a relative diminution of the bile acids and their salts which are responsible for maintaining cholesterol bile pigment, and calcium in colloidal suspension. This decrease in bile salts is caused by their more or less selective absorption through the

gall-bladder walls into the capillary channels of the lymph stream and blood stream.

The second primary alteration is a radical change in the secretion of mucoid substances by the mucosa of the gall bladder. This change may be quantitative as well as qualitative, but probably qualitative alterations are more important. The physical differences which occur in mucin and related secretions of the mucosa of the gall bladder as well as of other mucosal surfaces of the body are well recognized but the chemical and pathological changes and their significance have not received the attention they deserve. In connection with the formation of gallstones, these mucoid substances, simultaneously with the reduction of bile acids must acquire some sort of coagulative property and form a binding substance and organic framework for the precipitated elements of the bile. Without this skeleton substance, bile sediments, which are frequently observed in the gall bladder bile ducts and bile obtained by duodenal drainage do not result in gallstones. The unincorporated precipitates are washed out of the bile passages and pass, usually harmlessly into the intestinal tract.

Combined changes, even to pathological degrees, in the absorptive and secretory functions of other structures that are lined with mucous membrane are not unknown or even unusual. Reactions of this type are most frequently observed in the mucosa and walls of the gastrointestinal tract, but nasal surfaces, bronchi, the walls of the prostatic acini and pancreatic ducts, and their mucous membranes under certain circumstances exhibit similar phenomena. In the gall bladder the colloidal dispersed elements normally concentrated and with discontinuous drainage may produce gallstones when the two alterations in the bile, which have been mentioned previously become effective, while in other parts of the body continuous drainage or lack of the cholesterol-bile-pigment-calcium complexes usually fails to cause calculi to form. The nearest approach to conditions comparable to those in the gall bladder occurs in the urinary tract and in the prostate gland where the corpora amylacea occasionally produce real concretions, and in the lungs, where similar structures form but very rarely become calcified.

The part that neurogenic factors play in the abnormalities of secretion and absorption has received increasing consideration. However neurological reactions sometimes are difficult to recognize or evaluate, particularly when exercised on internal organs. Also it must not be forgotten that the so-called dysfunctional states of the vegetative nervous system so well emphasized by

¹The expression "sex hormones" is misleading and inadequate. It is undoubtedly true that many purely sexual functions of the body are directly influenced by fairly specific hormones, but these are so closely interrelated with and, at times, with all the other hormones of the body that every vegetative, voluntary and psychic activity of the individual may be affected by them.

in the normal bile were judged to be sufficient evidence in support of their conclusions and often justified for them, the removal of normal gall bladders. The advent of more logical explanations for both of these conditions, such as neurogenic dysfunction and the colloid theories of gallstone formation, has largely replaced the earlier notion of an infectious foundation for many diseases of the biliary tract. This theory, aside from the fact that any theory which presupposes a bacterial infection profound enough to cause gallstones or to cause signs and symptoms of cholelithiasis when stones are not present and still produce no permanent alteration in the anatomic structures, is so contrary to all modern conceptions of infection and its results that only an insufficient knowledge of these conditions could excuse such faulty reasoning. This chapter in the development of knowledge of the pathogenesis of gallstones is an interesting example of the many devious trails which must be followed before well established truths come to light.

SUMMARY

The principal data and theories embodied in the five important factors advanced in the past to explain the formation of gallstones have now been explored in some detail. Also, seven more or less fundamental facts about gallstones and their occurrence have been presented. Some dead wood, such as stasis, infection irritative catarrhal cholangitis, and significant association with any other disease, has been cleared away. Furthermore it

Even more necessary is the effort to distinguish sharply the effects of gallstones and the resulting clinical disturbances from the noncalculous causes of the biliary system, which occasionally lead to similar symptoms and discouraging attempts to effect relief.

ceptance of the seven fairly well established facts about gallstones considerably narrows the field in which the ultimate etiologic determinants must operate. Any theory which adequately accounts for cholelithiasis must conform to these limitations and must also include and harmonize the remainder of the pertinent data which have been collected about this subject during the past several centuries.

Such a theory must explain why gallstones occur in both men and women, but more frequently and at an earlier age in the latter than in the former why they are formed almost exclusively during that period of life when sex functions are active why they are primarily almost without exception, formed in the gall bladder and without any demonstrable anatomic changes in the wall of the gall bladder why they are produced during periods comparatively short in duration occasionally in showers or "litters" never continuously and which periods are rarely repeated and finally why gallstones tend to be rounded when not subject to molding influences by the wall of the gall bladder or by apposition to each other.

With these conditions in mind the conclusion becomes almost inescapable that gallstones occur only when there is a profound disturbance of biliary physiology induced by pathological deviations of hormonally controlled functions. Also in all probability the hormones which are concerned in this dysfunctional attack are those commonly designated as sex hormones although any or all of the other hormones may be involved¹.

In order to produce gallstones this functional disturbance must result in at least two primary changes in the normal physiology of the gall bladder. One is an alteration in the composition of the bile. Theoretically this alteration might occur as a result of an abnormal secretory function of the liver cells. The characteristics of the bile are often profoundly affected by pathological changes in the hepatic parenchyma, but there is little evidence to connect these with cholelithiasis. As previously emphasized the changes in the constituents of the bile which lead to the formation of gallstones occur primarily in the gall bladder. So far as is now known, the most important of these changes is a relative diminution of the bile acids and their salts, which are responsible for maintaining cholesterol, bile pigment, and calcium in colloidal suspension. This decrease in bile salts is caused by their more or less selective absorption through the

gall-bladder walls into the capillary channels of the lymph stream and blood stream.

The second primary alteration is a radical change in the secretion of mucoid substances by the mucosa of the gall bladder. This change may be quantitative as well as qualitative but probably qualitative alterations are more important. The physical differences which occur in mucin and related secretions of the mucosa of the gall bladder as well as of other mucosal surfaces of the body are well recognized but the chemical and pathological changes and their significance have not received the attention they deserve. In connection with the formation of gallstones, these mucoid substances, simultaneously with the reduction of bile acids, must acquire some sort of coagulative property and form a binding substance and organic framework for the precipitated elements of the bile. Without this skeleton substance, bile sediments, which are frequently observed in the gall bladder bile ducts, and bile obtained by duodenal drainage, do not result in gallstones. The unincorporated precipitates are washed out of the bile passages and pass, usually harmlessly into the intestinal tract.

Combined changes even to pathological degrees, in the absorptive and secretory functions of other structures that are lined with mucous membrane are not unknown or even unusual. Reactions of this type are most frequently observed in the mucosa and walls of the gastrointestinal tract, but nasal surfaces bronchi, the walls of the prostatic acini and pancreatic ducts and their mucous membranes under certain circumstances exhibit similar phenomena. In the gall bladder the colloidal dispersed elements, normally concentrated and with discontinuous drainage, may produce gallstones when the two alterations in the bile which have been mentioned previously become effective while in other parts of the body continuous drainage or lack of the cholesterol bile-pigment-calcium complexes usually fails to cause calculi to form. The nearest approach to conditions comparable to those in the gall bladder occurs in the urinary tract and in the prostate gland where the corpora amyloacea occasionally produce real concretions and in the lungs, where similar structures form but very rarely become calcified.

The part that neurogenic factors play in the abnormalities of secretion and absorption has received increasing consideration. However neurological reactions sometimes are difficult to recognize or evaluate particularly when exercised on internal organs. Also it must not be forgotten that the so-called dysfunctional states of the vegetative nervous system so well emphasized by

¹The expression "sex hormones" is misleading and inadequate. It is undoubtedly true that many purely sexual functions of the body are undoubtedly influenced by fairly specific hormones, but these are so closely interrelated with most, and, at times, with all the other hormones of the body that every vegetative, voluntary and psychic activity of the individual may be affected by them.

Westphal and his followers, are often preceded by pronounced psychic and other disturbances of the central nervous system. Gundermann (1930) in a discussion of biliary disease suggested that excitement such as anger or emotional upsets, might act as a cause. He located disorders of this nature in the region of the third ventricle of the brain. These emotional crises in turn according to him react on the vegetative nervous system. Weiss and English, in their book *Psychosomatic Medicine* (1943) wrote "The role of the emotions in the possible development of gall tract disease, in the precipitation of attacks of colic is a matter with which general medicine has not sufficiently concerned itself."

Functional and organic changes, chiefly in the hypothalamic region of the brain, undoubtedly influence secretory activities of the epithelial cells probably largely through alterations in vasomotor control. The cause of so-called peptic ulcers more and more has been ascribed to pathological psychical disturbances in these brain centers.

The exact mechanism by which attacks of hormonally excited neurogenic dysfunction associated with emotional upsets causes the wall of the undamaged gall bladder to absorb bile acids selectively and at the same time to secrete a pathological mucoid substance has not been demonstrated. Disordered sex functions probably play a major role, and as these are more prominently displayed by women than by men they account for the preponderance of the formation of gallstones during the active sex life of women. More study is needed to discover the nature of these upsets. They must have a fairly common pattern, they must occur on very infrequent occasions, and they should be detectable and perhaps preventable.

CONCLUSIONS

1. It is a well established fact that women are more liable to have gallstones than are men.

2. Gallstones occur almost exclusively in both men and women during the time of life when sex functions are active.

3. Any explanation of why gallstones are formed must be in harmony with these two facts.

4. The production of gallstones takes place, as a rule, only in the gall bladder.

5. Neither abnormal stasis of bile nor bacterial infection nor other disease is responsible for cholelithiasis.

6. The clinical symptoms and signs produced by the presence of gallstones have no relation to the etiologic factors of their formation and often occur many years after the gallstones are produced. Most gallstones, at the time of their in-

ception and often for many years afterward, are relatively silent.

7. Cholesterol, the chief constituent of gallstones, together with bile pigments and calcium, is normally held in a state of colloidal dispersion by bile acids and their salts.

8. A relative excess of cholesterol or decrease of bile salts may lead to a precipitation of the colloidal suspended elements of the bile.

9. A binding substance, most likely an excess of changed mucin or other related nucleo-albumin serves to mold and preserve the precipitated substances in the form of calculi. There is little evidence that mucin or nucleo-albumin can act as a precipitating medium.

10. In order that gallstones may be formed there must be simultaneous disturbances in both the absorptive and secretory function of the mucosa of the gall bladder and its walls.

11. During the time of active sex life of both men and women, neurogenic hormonally controlled disturbances, both in the central and the vegetative nervous systems, are frequent and occasionally cause profound functional changes, particularly in the vascular system, smooth muscles, and secretions. These influences are more pronounced in women than in men, but in both they at times cause serious alterations in the absorptive and secretory functions of the gall bladder produce a changed mucin or mucoid substance in the bile, and disturb the normal balance or ratio of cholesterol and bile salts.

12. Gallstones are primarily the result of functional disturbances which are effective only on infrequent occasions and are active over comparatively short periods of time although repetitions of their effects, as well as complications due to obstructive phenomena or secondary infections may at times, occur.

13. Functional upsets, primarily but not always, responsible for gallstones, should be distinguished from secondary or subsequent pathological conditions which often cause clearly recognizable and occasionally serious clinical diseases.

14. More study is indicated in order that the psychic and other neurogenic disturbances which produce gallstones may be recognized while in action and thus afford a sound basis for prophylaxis and treatment.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Wolf, J. W.: Thrombosis of the Cavernous Sinus with Hemolytic Streptococcal Bacteremia; Treatment by the Intravenous Injection of Sulfadiazine and Penicillin with Recovery. *Arch. Otolaryng. Chlc.*, 1944, 40: 33.

Wolf states that a boy of ten years made a complete recovery from thrombosis of the cavernous sinus with multiple thrombi in the right lung and kidney and hemolytic streptococcus bacteremia. The source of infection was a furuncle on the bridge of the nose. The therapeutic agents were sulfadiazine and penicillin. A total of 500,000 Oxford units of penicillin and 64 gm. of sulfadiazine was administered in a period of nineteen days. No ill effects were noted during the course of treatment.

Apologies were offered because the author did not confine himself to one therapeutic agent. However in view of the severity of the conditions present and the failure of sulfadiazine therapy in a previous case in the same hospital under another physician's care the author believed that the risk was too great to depend on one drug. Furthermore although he believed that he might be grossly criticized he stated that sulfadiazine given in large doses to produce a blood level of 18 mgm. or more per 100 cc. had a definite curative effect on septicemia, especially that caused by staphylococci, which bacilli were undoubtedly present in the original focus.

The author also points out that not until the blood level was 18 mgm. + did the disease show signs of abating, and that when either drug was used exclusively no change in the course of the disease was noted. Thus it is apparent that thrombosis of the cavernous sinus, a disease looked upon in the past as inevitably fatal, may now be cured by the use of large doses of a sulfonamide drug in combination with penicillin; however the patient must be kept under close observation.

JAMES C. BRASWELL, M.D.

Nicholson W. M., and Anderson, W. B.: Penicillin in the Treatment of Cavernous-Sinus Thrombophlebitis; Recovery with Unilateral Ascending Optic Atrophy. *J. Am. Med. Assoc.* 1944 126: 2.

A thirty year-old male was admitted to the hospital in a stuporous condition four days after the appearance of a small furuncle in the right anterior nares. A blow on the bridge of the nose the day after the onset was followed by pain, frontal headache and a chill within twenty-four hours.

On admission there was high fever, hemolytic staphylococcus bacteremia, bilateral exophthalmos, chemosis of the conjunctiva, edema of the face and

a dusky red discoloration of the skin indicating venous obstruction. A blood concentration of 75 mgm. per cent of sulfadiazine was determined on admission and an additional 7 gm. in twelve hours produced no improvement.

Penicillin was given for fourteen days, treatment starting with one intravenous dose of 10,000 units followed by subcutaneous injections totalling from 30,000 to 50,000 units daily. A return of headache and fever after five days was followed by a further course of penicillin for eight days at the rate of 30,000 units daily and in thirty-eight days the patient was able to leave the hospital.

On the twenty-second day, when the right eye could first be opened, it was found that vision was reduced to light perception and has so remained.

There was increased perivascular sheathing with constrictions of the proximal portions of the retinal artery and papilledema resulting in optic atrophy. The optic atrophy was probably secondary to embarrassment of the arterial circulation with ischemia and later edema of the retina. I.e. it was an ascending degeneration. JOHN R. LINDSEY M.D.

EYE

Siegel, R.: Buccal Mucous Membrane Grafts in Treatment of Burns of the Eye. *Arch. Ophth. Chlc.* 1944, 3: 64.

The author stresses the importance of immediate transplantation of buccal mucous membrane in the treatment of conjunctival and corneconjunctival burns. There are three stages of burns of the eye: simple inflammation, profuse exudation and necrosis. Grafting with mucous membrane should be done in cases of direct burns of the cornea with destruction of the perilimbal circulation. In direct burns of the cornea with questionable perilimbal circulation and in burns of the eyeball in which the cornea is not involved but in which the perilimbal circulation is destroyed.

Prompt grafting stimulates vascularization (which in turn provides nourishment to the cornea) and prevents formation of scar tissue with resultant symblepharon. With the exception of cases in which the entire perilimbal circulation is totally and irreversibly destroyed, grafting of mucous membrane shortens the healing process and offers a better prognosis.

In 5 cases of this series buccal mucous membrane was grafted and in 3 cases no grafting was done. Siegel concludes that every grave conjunctival or corneconjunctival burn should be treated by means of a graft of buccal mucous membrane as soon as possible after the injury if the vascular supply to the cornea is destroyed, especially in cases exposed to

war gases in which there is vascular interference in the perilimbal circulation. Preserved heterogenous conjunctiva and cadaver conjunctiva require further clinical trial.

JOSUVA ZUCKERMAN, M.D.

Stallard, H. B.: Retinal Detachment; 78 Cases in the Middle East. *Brit. M. J.*, 1944, 2, 339.

The results obtained in a series of 78 cases of detachment of the retina in the Middle East are reported. In discussing the management of this condition the author states that accurate localization of the tear or tears in the retina is essential. The edges of the tear are made to adhere by electrocoagulation, i.e. by diathermy applied to the surface of the sclera and penetrating the sclera and choroid to reach, but not to enter the retina. Fluid beneath the detachment is drained by penetrating diathermy needle punctures and suction or by trephining of the sclera puncture of the choroid and the production of choroidoretinal adhesions around the tear.

Of the 78 cases of retinal detachment 76 were operated upon by one technique operation was contraindicated in one case, and spontaneous recovery occurred in another. The procedure in these cases was a combination of surface diathermy of from 90 to 100 ma. applied for a period of eight seconds around the edges of the tear or several tears and penetrating diathermy. One or two (very rarely more than two) punctures were made in the sclera with a diathermy needle, and a current of 40 ma. was applied for one second. The inter retinal fluid was aspirated by a glass tube and rubber suction bulb applied to the sclera over the site of the diathermy penetration.

In this series there were 13 cases of cystic degeneration, 21 of chorioidoretinal degeneration, 3 of myopia, 23 of civil trauma, and 18 cases of military trauma. In the 13 cases of cystic degeneration the retina was successfully replaced, the tear was sealed and the visual field restored. In the 21 cases of chorioidoretinal degeneration the retina was replaced and the visual field restored. In the 3 cases of myopia, the retina was successfully replaced in 2 cases, and in the third case operation was followed by a vitreous hemorrhage and a localized retinal detachment. In 20 of the 23 cases of detachment following civil trauma, the operation was successful. Operation was done in 16 of the 18 cases of detachment following military trauma, and in 10 of these the retina was completely replaced.

The prognosis depends upon the type of case. It is favorable in early cases with a small retinal tear which is easily accessible, particularly if operation is performed within a month of the onset of the detachment, and more favorable if the tear is in the lower half of the retina.

JOSUVA ZUCKERMAN, M.D.

EAR

Campbell, P. A.: The Progress of Aviation Otolaryngology in World War II. *Laryngoscope*, 1944, 54, 387.

The author discusses a number of recent changes in various aspects of aviation otology. Up to date

considerable research effort has been expended in improving our concepts and adding to our knowledge of aviation otology. Advances have been made in determining the effect of aircraft noise upon the ear and the effect of noise upon communications intelligibility. A number of tests are in the process of development. Protection against noise and research in airsickness also show promising developments. Campbell believes that much excellent work will probably go unreported in detail until the war is over.

NOAH D. FABRICANT, M.D.

Collins, E. G.: Injury to the Ear Among Battle Casualties of the Western Desert. *J. Lar. Otol. Lond.*, 1944, 59, 1.

In this investigation of 885 battle casualties of all types it was found that 1 in every 5 patients sustained some aural trauma, which was usually due to blast. The unit distribution of the patients and the types of battle casualties are shown in addition to the type of missile which caused the injuries.

In the majority of patients the aural injury consisted of a rupture of the tympanic membrane which was accompanied by an initial mixed inner and middle ear deafness in about 40 per cent of the patients with traumatic perforations. The percentage of patients with rupture of the tympanic membrane who are left with residual deafness is undetermined but is not considered to be negligible.

The effect of blast on the anatomical parts of the ear is discussed. Twenty two per cent of the traumatic perforations became infected.

Some observations are made on prophylaxis and the forms of treatment which proved of value.

JOHN F. DEXLER, M.D.

Birrell, J. F.: A Comparative Report on Ear, Nose and Throat Injury in the Army at Home and Overseas. *J. Lar. Otol.*, Lond., 1944, 59, 16.

The author has kept accurate notes on all of the cases which were examined and treated during his service as an Army ear, nose and throat specialist in a Military Hospital at home and in a General Hospital attached to the British North African Force. The article is replete with many tables and comparative figures on various phases of otolaryngology and certain conclusions and opinions are given.

There was a higher proportion of ear cases seen overseas than at home. These comprised a large percentage of otitis externa, but there was a marked similarity in the number of chronic cases of otitis media which were observed. Of the 4,000 unselected cases 57 per cent were aural. The most common conditions are chronic otitis media, otitis externa, chronic sinusitis and chronic tonsillitis in the order given.

JOHN F. DEXLER, M.D.

Brunner, H.: The Present Status of Diagnosis and Management of Ménière's Syndrome. *Arch. Otol. Chlc.*, 1944, 40, 38.

Brunner states that the typical Ménière attack consists of tinnitus, diminution of hearing, labyrinth

thine vertigo and spontaneous nystagmus. Only vertigo of the type which can be produced by the usual clinical methods of examining the labyrinth should be considered as labyrinthine.

Marked spontaneous nystagmus between Ménière attacks is not of labyrinthine origin. It indicates an organic disease in the posterior cranial fossa.

If the attacks consist only of labyrinthine or only of cochlear symptoms, a definite diagnosis cannot be made unless the patient is under longer observation.

During remission the patient is either normal, or, if the injury is progressive, he will present gradual diminution of function of the inner ear.

If there is a systemic, cerebral or aural cause the syndrome is called "symptomatic Ménière's syndrome." When no etiological factor can be determined the disease is designated "idiopathic Ménière's syndrome." The pathological changes are apparently the same in both cases.

Concerning the cause of Ménière's syndrome the metabolic theory and the vascular theory are offered. The metabolic theory is not supported by microscopic observation of the human ear as well as by experiment, and it explains the pathological picture of the idiopathic as well as the symptomatic Ménière's syndrome, although further studies are necessary.

Most frequently the angioneurotic disturbances within the internal ear are due to arteriosclerosis of the brain. Incipient arteriosclerosis of the brain should be taken into consideration in any case of Ménière's syndrome in which the first attack takes place between the third and the fifth decade of life and in which there is no evidence of another cause such as tabes, injury of the head or small tumor of the acoustic nerve.

Among the systemic diseases various types of leucemia, syphilis, influenza, malaria, virus infection, and particularly focal infection may cause the symptomatic Ménière's syndrome.

Allergy is occasionally but not frequently a cause of the symptomatic Ménière's syndrome.

Among the aural diseases a chronic adhesive process of the tympanic cavity is frequently found to cause the symptomatic Ménière's syndrome.

Concerning treatment, a Ménière neurosis must be excluded. When Ménière's syndrome is symptomatic, the etiological disease should be treated. There is no satisfactory treatment for the idiopathic Ménière's syndrome. Surgical intervention is indicated if the diagnosis of Ménière's syndrome is certain, if conservative measures have been exhausted, and if the disease is progressive on one side while the other ear is normal.

NOSE AND SINUSES

Ruskin, S. L.: Vitamin C-Sulfonamide Compounds in the Healing of Wounds; The Use of Sulfanilamide Ascorbate in the Treatment of Chronic Suppuration of the Wound After Radical Blunt Osteotomy. *Arch. Otolaryng.*, 1944, 4, 15.

The role of vitamin C in wound healing, declares Ruskin is now firmly established and its routine

use in all surgical and traumatic cases is indicated. It should also be used in conjunction with other therapeutic agents in cases of infection. Ascorbic acid stimulates the healing of wounds and counteracts the delay in healing incident to the use of sulfonamide compounds. Sulfanilamide ascorbate and sulfathiazole ascorbate both show a definite capacity to heal chronic suppurative otitic infections and to stimulate healing with epithelization.

NOAH D. FARRCAST, M.D.

Dandy, W. E.: The Treatment of Rhinorrhea and Otorrhea. *Arch. Surg.* 1944, 49, 75.

Rhinorrhea and otorrhea are due to the presence of a fistula connecting the cerebrospinal spaces with the exterior. Pneumocephalus may be associated with this condition. The two great causes of rhinorrhea and otorrhea are fractures of the skull and openings created by surgical procedures. Less frequent causes are erosion by tumors or infection, and congenital abnormalities. Post-traumatic otorrhea will usually stop in less than two weeks and there is consequently no indication for surgical intervention. Fistulas into the frontal or ethmoid sinuses or fistulas created by operation on the mastoid are frequently slow to heal or may close and reopen periodically.

A cerebrospinal fistula is always a potential source of meningitis or brain abscess. A fistula should never be left open longer than two weeks unless the fluid is unmistakably diminishing.

When rhinorrhea follows an operative procedure, the site of the fistula is along the path of the operative attack. It is, therefore, not usually difficult to find. If the fistula follows a depressed skull fracture, the depression may indicate its position. If there is no depression, roentgenograms including the frontal, ethmoid, and sphenoid sinuses are extremely important. In frontal craniotomy an unusually large frontal sinus may be opened. It is of the greatest importance that the surgeon should always know the size of the frontal sinus as demonstrated in roentgenograms before he uses a low frontal approach. When a frontal sinus is opened a flap of dura can be reflected over the opening and tightly sutured to the overlying galea. If the opening is disclosed by rhinorrhea after the operation is completed, the wound should be reopened immediately and the procedure carried out. During cerebellar operation a mastoid cell is occasionally opened in this event the dura should be immediately sutured over it to prevent immediate or subsequent infection.

In 3 of 4 cases in this series in which otorrhea followed operation on the mastoid, the bony defect was in the roof of the petrous bone about 3 cm. beside of the lateral wall of the skull. Therefore, this is the logical place to look for the fistula. The corresponding dural defect can be sutured and, if necessary, re-enforced by a piece of fascia lata or more conveniently by a layer of the sheath of the temporal muscle. If the dural defect is near the surface the fascia is sutured in place. If the fascia is too

stick it can be laid over the suture line and treated with a 3.5 per cent solution of iodine to promote adhesions.

The author has encountered 11 cases in nearly twenty years and these are reported in some detail.

HAROLD C. OCHSNER, M.D.

MOUTH

Somervell T. H.: Recent Advances in the Treatment of Carcinoma of the Mouth and Jaws. *Brit J Surg* 1944 32 35

Epithelioma of the mouth is so common as to be considered indigenous in the coastal districts of South India and Ceylon. In a 200-bed hospital at Travancore 500 operations have been done yearly for malignant diseases of which nearly 75 per cent occurred in the mouth. The site was the cheek lips, or lower jaw in 80 per cent, the tongue in 13 per cent and the upper jaw in 7 per cent. This high incidence of cancer of the mouth is attributed to the use of tobacco along with the betel leaf and areca nut. The combination of lime made from shells with two particular brands of tobacco used in that area is considered to be the most important etiological factor.

The treatment most suited to the various regions is discussed. Cancer of the cheek and lip is removed

by diathermy with implantation of radium needles at the time of operation followed later by resection of the glands and the further implantation of radium. Extraction of the teeth and removal of the glands is done after removal of the growth. For cancer of the jaws surgical removal is preferred with removal of the glands and the insertion of radium needles. Chloroform has been found the most suitable anesthetic.

Cancer of the tongue if involving only the tip may be removed by diathermy otherwise it is treated by the insertion of radium needles and later resection of the glands.

Cancer of the tonsil the epiglottis and the nasopharynx is treated with radium needles. Removal of one side of the hard palate may be necessary to permit access to the nasopharynx.

Glands of the neck are removed surgically and radium needles implanted at operation when complete removal is questionable.

The necessity of radical surgery is emphasized along with the liberal use of radium needles, which must be available for insertion at the time of operation.

Deep x ray therapy has been generally unsatisfactory in the author's experience.

JOHN R. LINDHAY, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Russell, W. R. and Harrington A. B.: Early Diagnosis of Peripheral Nerve Injuries in Battle Casualties *Br J M J* 1944 2 4

Delay in the early diagnosis of peripheral nerve injuries following war wounds has gravely prejudiced the subsequent usefulness of limbs in many cases according to the study made by the authors. They stress the importance of an early examination for peripheral-nerve injuries and outline the salient points in diagnosing peripheral nerve lesions of the upper and lower extremities. Motor and sensory tests can be carried out, in a high percentage of patients in a very few minutes and a record made of the nerves involved and the relative extent of their injuries.

The authors have described, in a clear concise fashion the important points in examination with reference to each of the major nerve trunks. They have also described certain unusual movements that can be accomplished by patients with complete paralysis of one nerve by substituting other muscles or because of an adjacent nerve overlap.

Suggestions are made as to a method of recording nerve function by chart, by lifting the major nerve trunks and giving estimates of the function in the muscles supplied by that particular nerve and by grading these estimates from 0 to 5 according to the amount of muscle contraction present.

One of the most important points in this article emphasizes the harm that may ensue to muscles and joints by extensive and improper splinting. It is advised that in forward surgery near the front, no effort or attempt be made to support paralyzed muscles except by using a sling and advising the patient to prevent overstretching of the paralyzed muscles as far as possible.

Extensive casts or splints have resulted in so-called frozen hands, which quickly lead to a damaging vicious cycle, as follows: the hand is kept immobile, the joints become stiff, the hand becomes painful, the patient is even more unwilling to move his hand, et cetera. The early active movement of joints should be encouraged. Passive exercise by the patient can often be carried out even when physical therapy is not available.

HOWARD A. BROWN, M.D.

Denny Brown, D., and Brenner C.: Lesion in Peripheral Nerve Resulting from Compression by Spring Clip *Arch. Year Psychiat., Chic.*, 944 53:1

Experiments have been conducted to determine the effect of a compression lesion of a peripheral nerve both insofar as the local changes in the nerve are concerned and with reference to its peripheral function as well.

A special spring clip was devised the tension of which could be measured in grams, and the experiments were performed on cats under pentobarbital-sodium anesthesia. The operative studies included different degrees of pressure and a varying time element with regard to the compression of the nerve. Subsequently the nerve was again exposed under anesthesia and stimulated electrically above and below the spring clip before the animal was sacrificed. Following this the nerves were fixed, stained with osmic acid and sectioned in paraffine or they were embedded in pyroxylin and stained by the Grobelschowsky the Nissl, or the iron hematoxylin method. As a control the sciatic nerve on the opposite leg was clamped with a hemostat for ten seconds, which produced a complete lesion. This allowed of comparison from the standpoint of function peripheral to the point of the lesion.

Metal clips exerting a tension of 170 up to 430 gm. left in place for two hours, produced a transient paralysis lasting from five to eighteen days. There was no demonstrable gross defect in sensation and the distal portion of the nerve fibers did not degenerate. Microscopic study revealed an intermittent loss of myelin at the nodes of Ranvier in the area compressed. This lesion is said to be identical with that produced by compression of the nerve with a tourniquet. Motor recovery was fairly early, but the restitution of the myelin defect was only slight at an interval of from six to eight weeks following the trauma and defects were still demonstrable after six months.

Clips having a very much lower degree of tension (2.5, and 7 gm.) were then used and these could be left in place as long as fourteen days without their producing any defect in conduction—whether tested by walking ability, placing reactions, spreading of the toes or reaction to pinch of the toe pads in the unanesthetized animal, or by stimulation of the exposed nerve above and below the clip with the animal under light anesthesia. Despite the lack of these changes, the compressed segment of nerve showed marked narrowing, and was edematous on either side of the region of constriction. There were rather marked histological changes present in the myelin and axis-cylinder in the edematous region. This appeared to be due to simple swelling of the myelin, and was associated with the mobilization of large pale endoneurial cells.

A 44-gm. clip, when left in place, produced a complete motor and sensory paralysis, and exploration after fifteen days revealed complete loss of all electrical excitability in both the sensory and motor fibers below the clip, and complete histological degeneration of all the fibers in the nerve and of all the motor and nerve endings with atrophy of the muscle fibers. The proximal degeneration was of the type due to excessive ischemia.

Continuous compression by clips of from 9 to 10 gm. produced delayed paralysis, which appeared on the fifth to the eighth day and lasted up to twenty five days with recovery without necessarily any wallerian degeneration or change in the nerve endings or muscles. There was however segmental loss of myelin and there were changes due to edema.

The effect of pressure on nerve is considered to be due entirely to ischemia and the characteristic histological lesion and dissociated paralysis form a distinctive type of neuropathological reaction. The histological evidence indicates that the dissociation between sensory and motor function is due to a functional property of the disorder of the axoplasm, and not to selective effects related to the size of the fibers.

HOWARD A. BROWN M.D.

Jelasma, F : Clinical Analysis of 1 000 Consecutive Cases of Low Back Pain with Particular Reference to Sciatic Pain Caused by Extrusion of the Intervertebral Disc. *South. M. J.*, 1944 37 372.

Clinical analysis of 1,000 consecutive cases of low back pain revealed the fact that 531 presented sufficient clinical signs and symptoms to warrant the assumption that a focal neurological lesion was present. The remainder or 469 did not present any focal neurological signs.

Of the 531 focal lesions approximately 9 per cent were due to conditions other than herniated disc. These conditions consisted of traumatic injury to the bodies of the vertebrae metastatic tumors of the spine spinal-cord tumors, and spina bifida occulta.

It was found that palliative measures and conservative treatment are definitely indicated and give good results.

In a very high percentage of cases the onset of the trouble can definitely be ascribed to injury.

The incidence is highest between the ages of thirty and forty, a time when men are still active yet the disc is definitely less able to withstand trauma.

Multiple intervertebral discs were found in 7 per cent of the cases.

The clinical syndrome of extruded discs in the lower lumbar region is well known to make the use of myelograms unnecessary except in a very few cases.

The results are favorable in the cases with definite root pain if the root is carefully explored and the lesion completely removed.

JOHN J. MALONEY M.D.

BRAIN AND ITS COVERINGS CRANIAL NERVES

Adrian, E. D : Localization in the Cerebrum and Cerebellum. *Brit. M. J.*, 1944 2 137

Attention is called to the newer methods of physiological technique with regard to the study of localization in the cerebrum and cerebellum. Animal studies made under anesthetics of the barbitalur group, are described first, with reference to stimulation of various portions of the retina, and the correlation

between this and electrical activity demonstrated in the striate area of the brain at the same time. Stimulation of various portions of the retina can be shown to affect different portions of the striate area from an electrical standpoint. A diagrammatic scheme is shown which indicates the localization of stimulation of various parts of the retina and its representation in the visual area of the monkey's brain.

The author describes his study of the nervous mechanism of the cochlea in cats and also in monkeys. He found that when the cochlea is stimulated by sound electrical activity appears in the appropriate region the upper surface of the superior temporal gyrus. With notes of low pitch the maximum activity in monkeys is in the anterolateral part of the receiving area, and with high notes in the posteromedian part of the receiving area. Thus it would appear that the apex of the cochlea supplies the anterolateral part and the basal turn the posteromedian part.

The relation of the brain to the sense organs is illustrated by the difference in the receiving areas of the brain in the cat and in the pig, with special reference to the forelimb area. In the cat one finds a very large forelimb area of representation in the cortex with individual areas representing the digit footpad etc. whereas in the pig the area chiefly represented is the snout, and it is difficult or impossible to detect anything at all from the limbs. This, presumably, is because the cat uses its forelimbs and claws in skilled movements which must be guided by sight and touch, whereas the pig uses its limbs for standing and walking, and for nothing else. All skilled movements of the pig are made by the snout, and this has an elaborate representation in the brain.

The author's study includes a brief discussion with regard to the role of the cerebellum. Here, localization has not been particularly satisfactory experimental work on animals would seem to indicate that impulses from the hindlimbs are registered more anteriorly in the cerebellum, while those of the face and head area appear to lie more posteriorly. A good deal of the cerebellum seems to lack any local representation of the body and limbs.

HOWARD A. BROWN M.D.

Babeon, B. G : Spontaneous Subarachnoid Hemorrhage in Infants and Its Relation to Hydrocephalus. *J. Pediat.* S. Louis, 1944, 25 63.

Blood in the spinal fluid of the newborn infant usually occurs as the result of birth trauma or hemorrhagic disease. These conditions are well established during the first week of life. Three cases are reported in which spontaneous hemorrhage occurred in infants between the ages of eighteen and thirty days. Two of the patients were siblings. The bleeding apparently developed suddenly without evidence of hemorrhage at any other point. Evidence of acute infection scurvy purpura hemophilia, or leucemia was lacking in all cases, and the late onset made hemorrhagic disease of the newborn infant seem unlikely. Subsidence of bleeding occurred

promptly in all cases and no cause for the bleeding could be determined. Two of the patients developed hydrocephalus. Of these one succumbed from pneumonia after operation was attempted to cauterize the choroid plexus; the other, now five years of age, has an arrested hydrocephalus of considerable size.

Spontaneous subarachnoid hemorrhage occurs in children about as frequently as in adults and although death and residual paralysis are common, approximately 50 per cent recover completely. The cause is generally rupture of a congenital defect in a cerebral vessel. This is presumed to be the cause in the cases reported since disease and dyscrasia were ruled out. The reaction of the blood on the meninges with resultant adhesion and obstruction to the free flow of cerebrospinal fluid is presumably the cause of the hydrocephalus. It is suggested that unrecognized subarachnoid hemorrhage at birth is a likely cause of varying degrees of hydrocephalus and that prompt and complete removal of blood may offer the best chance of avoiding acquired hydrocephalus from such hemorrhage. JAMES L. LINDQUIST, M.D.

Newhill, H. P., and Anderson, G. C.: Racial and Sexual Incidence of Primary Intracranial Tumors: Statistical Study of 123 Cases Verified by Autopsy. *Arch. Nerv. Psychiat.* Chlc. 1944, 51: 364.

This is a statistical study based on the records of 6,112 consecutive autopsies of patients between the ages of one month and seventy years. It was conducted in a hospital which has a large number of negro patients. More than half of the autopsies were carried out on negroes. In the series 131 primary intracranial tumors were observed. Forty-five occurred in members of the negro race and 88 in members of the white race. Thus 1 of 47 white patients on whom autopsy was performed had a primary intracranial tumor while only 1 of 132 negro patients had such a tumor. This is more significant when one knows that 1,752 more autopsies were carried out on negroes than on white persons.

Very carefully prepared statistical tables are available and certain interesting conclusions were reached. Gliomas occurred twice as frequently in the white race as in the negro. This tumor was most frequently found in white females. Meningioma was three times as frequent in white persons as in negroes. Of the 28 meningiomas which were found, 12 occurred in white females. Other intracranial tumors showed no sexual or racial predilections.

ADAM V. VAN DUSEN, M.D.

SPINAL CORD AND ITS COVERINGS

Badal, D., Munro, D., and Lamb, M. E.: The Clinical Significance of Bacteriuria in Patients with Spinal-Cord Injuries. *N. England J. M.* 1944, 830: 683.

The most common organisms found in the urine of patients with spinal-cord injuries are the proteus vulgaris, Escherichia coli, alpha hemolytic strepto-

coccus, enterococcus, and staphylococcus. The presence of bacteria in the urine does not necessarily imply infection. Infection is manifested by chills and fever and the presence of 100 or more white cells per high power field in the urine.

Bacteriuria will develop in all cases with an indwelling catheter by the end of the first seventy-two hours. Sterilization of the urine in the presence of an indwelling catheter used as part of the tidal drainage apparatus has been impossible except by withdrawal of the catheter and is unnecessary provided that the latest type of apparatus is used and is properly adjusted to the bladder it is serving. Infection of the urinary tract as evidenced by the symptoms and signs of cystitis, pyelitis, and urethritis in a patient with a spinal-cord injury who is being treated with tidal drainage is best controlled by proper adjustment of the apparatus, bed rest, and the administration of large amounts (5,000 cc.) of fluid daily.

Patients who have had a spinal-cord injury and recover can expect to have a normal genitourinary tract with normal function and without bacteriuria, unless they have had a transection of the cord, a renal or bladder stone, a draining perineural abscess, or a lesion that has produced permanent physiological or anatomic denervation of the bladder. If such a patient has a transected spinal cord he can expect a reflex bladder without bacteriuria. If such a patient has had a physiological or anatomic denervation of the bladder he can expect a shrunken, useless bladder with bacteriuria and recurrent bouts of pyelitis. DAVID JOHN LEVINSKY, M.D.

French, J. D., and Payne, J. T.: Cauda-Equina Compression Syndrome with Herniated Nucleus Pulposus: A Report of 8 Cases. *Ann. Surg.* 1944, 70: 73.

Herniation of the nucleus pulposus in its more common form has been well described in the literature, but little can be found concerning extensive protrusions. The authors describe 8 cases of massive nucleus-pulposus protrusions in which the lesions produced either a complete or partial subarachnoid block with cauda-equina compression. The history of these patients so closely resembles that of patients with cauda-equina tumors that a differential diagnosis is difficult. In the authors' experience cauda-equina compression occurs more often from herniated nucleus pulposus than from tumor.

The duration of the symptoms varied from three weeks to thirty years. Most of the patients suffered a short, rapidly progressing period of incapacity just before their entry into the hospital. In none of the patients was there a history of a severe injury. The pathological process was found at L₁, L₄, and L₅. In all cases it severely compressed the dorsal sac. In 3 cases there was thickening of the arachnoid with matting of the cauda equina. In 2 of these cases this was present to the extent that obstruction remained after removal of the extruded nucleus pulposus.

There is considerable similarity in the symptoms. The main complaints were pain in the back and both legs, numbness in the saddle area and/or both legs, weakness and sphincter disturbances. The signs were also similar. These consisted of weakness or atrophy in the gluteal region or legs, sensory changes in both legs, multiple changes in the knee and ankle jerks and sphincter abnormalities. A narrowed interspace at the level of the protrusion was often found. This is an important diagnostic point in differentiating nucleus pulposus from tumor. The total protein of the spinal fluid varied from 60 to 630 mgm. per cent. DAVID JOHN IMPASTATO M.D.

MISCELLANEOUS

Friedman A. P., and Brenner C.: Post Traumatic and Histamine Headache *Arch. Neur. Psychiat.* Chic., 1944, 53: 126

This study represents an investigation of the relationship between the mechanism of post traumatic and histamine headache. Twenty two patients with a history of post traumatic headache were given 0.1 mgm. of histamine base (0.175 mgm. of histamine diphosphate) intravenously. The prompt decrease in systolic blood pressure occurring after the injection

of histamine was followed by a secondary rise in pressure of corresponding degree. Headache developed as the blood pressure was rising. The rise in pressure appears to be due to a reflex response of the sympathetic nervous system secondary to the immediate changes produced by histamine.

The headaches produced by this injection were identical in character and location with the post traumatic headaches experienced by 13 patients and were strikingly similar to those experienced by 3 patients. The results were particularly significant in those patients with asymmetric or unilateral post traumatic headaches accurately reproduced by histamine injection. It is reasonable to conclude that histamine activated the physiological mechanism involved in the production of post traumatic headache.

The majority of patients with histamine headache obtained some relief by sitting upright. This is inconsistent with reports that lowering of the intracranial pressure of the cerebrospinal fluid aggravates histamine headache.

A few patients who could be followed up reported a decided diminution in the frequency and severity of their headaches after they received the injection.

JOHN L. LAMOUR M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

D. Abreu, A. L., Litchfield, J. W., and Hodson, C. J.: Major Complications of Penetrating Wounds of the Chest. *Lancet* Lond., 1944, 247 197

The authors discuss several hundred penetrating wounds of the chest which occurred in Italy where infection seems to have been more prevalent than in North Africa. Most of the wounds were received from two to forty days prior to admittance of these cases at the General Hospital where the authors worked. There were 125 patients with uninfected hemothorax 77 with pyothorax, 34 with abdominal-thoracic wounds, 44 with proved atelectasis 16 with lung abscesses 23 with bronchopleural fistulas, 11 with extrapleural hemothorax and 84 with retained intrathoracic missiles (pulmonary in 55 pleural in 15 and mediastinal in 14).

There were 15 deaths 11 occurred one month after the injury. Gross empyema was the cause of death in 13 cases 1 patient died as a result of a heart wound and 1 from a severed thoracic duct.

Patients with uninfected hemothorax were treated by thorough aspiration and breathing exercises and all but the smallest effusions were aspirated. Air replacement was not given except to relieve respiratory distress or to aid in roentgenological diagnosis. Of 131 cases of hemothorax without any evidence of infection, 125 were rendered fluid-free and 5 became infected. Clotting in a hemothorax is often due to infection.

Seventy-seven cases of pyothorax with 13 deaths should correct any undue optimism with regard to penetrating wounds of the chest. The ideal treatment is to aspirate fluid until the lung has re-expanded enough to permit localization of the pus to a pocket. In the very grave cases surgery could not be delayed long enough to permit re-expansion of the lung and localization of the pus. The advent of penicillin has aided in checking the severe toxemia, and in delaying or avoiding, operation in some of these cases. Hour-glass saddle-shaped and multi-locular empyema cavities required the breaking down of some adhesions at operation. The procedure in such cases is described.

After operation, full drainage must be maintained. A constant watch by roentgenography must be kept on the size of the cavity and the open tube is kept in place until a pleurogram proves that no empyema cavity remains.

Penicillin therapy is of great value, its chief use is in the form of intrapleural instillation of the sodium salt combined with aspiration of infected pleural fluid and many heavily infected effusions have been sterilized. The authors describe the method of its use in the closure of infected wounds of the chest wall.

The late complications of 34 thoracoabdominal wounds included empyema, hemothorax, pleuro-biliary fistulas diaphragmatic tears subpleural abscess and pneumoperitoneum.

EARL O. LATIMER, M.D.

Parsons, W. H., Henthorne, J. C., and Clark, E. L., Jr.: Plasma-Cell Mastitis: Report of 5 Additional Cases. *Arch. Surg.* 1944, 49 86.

Since Adair described plasma-cell mastitis as a clinical entity in 1935 there have been approximately 45 cases reported. This lesion is characterized by a unilateral painless tumor which occurs in parous women. Sometimes mild and evanescent signs of inflammation are present in the course of its development, and occasionally there is a watery or creamy discharge from the nipple. Its most distinctive clinical feature is its striking resemblance to mammary carcinoma. It is not unusually tender. Often it is so adherent to the skin as to produce orange peel dimpling. The nipple is frequently retracted and the axillary lymph nodes are likely to be enlarged.

The gross lesion of plasma-cell mastitis appears as a yellowish brown discoloration of the mammary tissue often associated with the formation of abscesses. The contents of the abscess and of the contiguous ducts are puriform or butterlike.

Histologically there is an ulceration of the duct epithelium, which is replaced by granulation tissue, the formation of foreign-body giant cells, and a periductal collection of plasma cells and other leukocytes. Sheaves of fatty acid crystals and other evidences of the presence of lipid substances, such as foamy histiocytes and droplets of fat within the plasma cells, have been described.

The authors observed 5 cases of plasma-cell mastitis in 1500 specimens of breast tissue examined. There was a recurrence of the lesion in 3 patients. There was diffuse comedonastitis coexisting in 1 case. One patient went through a normal pregnancy in the same year that her breast was removed without the development of mastitis in the remaining breast. In 1 patient who had both ovaries removed five years prior to the onset of symptoms referable to the breast, the course of the plasma-cell mastitis covered three years which is an unusually prolonged time for this condition. EARL O. LATIMER, M.D.

TRACHEA, LUNGS, AND PLEURA

Goorwitch, J.: Closed Intrapleural Pneumothorax. *J. Thorac. Surg.* 1944, 3 5.

This study deals with the author's personal experience with internal pneumonolysis as well as an analysis of over 7,000 cases reported in the literature since 1924. The series includes 55 operations performed by the author on 50 lungs of 48 patients, as

well as 2043 cases collected from the literature by Moore from 1924 to 1932 and 5114 cases collected by the author from the literature from 1933 to 1944.

As a rule more adhesions were found thoroscopically than would be expected from a study of the roentgenograms. Complications occurring in the author's cases included fever in 44 per cent, serous effusion in 11 per cent, spontaneous pneumothorax in 3.6 per cent, extension of the disease in 3.6 per cent and hemorrhage, severe emphysema, and obliterative pleuritis each in 1.8 per cent.

In the collected cases fever was found to occur in about one fourth of the cases, hemorrhage was infrequent but accounted for 9 deaths among more than 7,000 cases, spontaneous pneumothorax is regarded as a serious complication and accounted for 9 per cent of all deaths in the collected series, pleural effusions occurred in about 25 per cent of the collected cases, bronchopleural fistulas and empyema occurred infrequently but they are the largest single cause of death.

In general the clinical results were reported as satisfactory in 75 per cent of the cases. The author believes, however, that this terminology should be discarded, as the clinical result depends on the effectiveness of the pneumothorax. Closed pneumonolysis is evaluated with respect to complications and clinical results. THOMAS F. THORNTON, JR., M.D.

Bayliss, C. G.: Closed Intrapleural Pneumonolysis.
Med J Australia 1944 2 129

Systematic, despite the great breadth of the subject treated, this disquisition begins with the history of artificial pneumothorax, to be followed by that of pneumonolysis and reviews the more recent literature on the structure of adhesions in pulmonary tuberculosis, the technique of operation (the author has employed exclusively the galvanocautery) anesthesia (nembutal, 3 gr. two hours before operation, and omnopon 0.5 per cent, with adrenalin 1 in 1000) and puncture sites. The author nearly always chooses the anterior axillary line for either the thoracoscope or the cautery, occasionally he chooses the posterior axillary line for the thoracoscope, the height of the puncture depending upon the location of the adhesions to be severed. The adhesions are "freed" released or enucleated rather than cut, the line of separation being external to the parietal pleura.

The basis of the report consists of 143 operations on 115 patients. In 65 of these individuals (56.5 per cent) complete pneumonolysis was accomplished, the presence of tubercles on the pleural surfaces not preventing the operation so long as they were not too close to the adhesion to be severed. In 35 per cent the operation remained incomplete and in 15 (13 per cent) a thoroscopic inspection was all that was attempted. The youngest patient operated upon was fifteen years of age. In 57 cases of this material, the disease was active in the contralateral lung at the time of operation, in 2 cases there was present roentgenographically a "doubtful" area. In

7 instances contralateral artificial pneumothorax was being maintained at the time of operation. The operation was always instituted as soon as possible, there was no waiting for the full attainable effects of the pneumothorax (in 35 patients artificial pneumothorax had been present for less than three months, in 34 from six to twelve months, in 6 from twelve to eighteen months, in 4, over eighteen months). The author has never countenanced artificial pneumothorax under positive pressure in an attempt to obtain better conditions for pneumonolysis.

It is considered that the operation was successful in 58 instances, unsuccessful in 48 (including 15 patients in whom pneumonolysis was not attempted). In 12 individuals the time has been too short to permit of final assessment of the results. Complications were hemorrhage (3 patients, in 1 the source was the thoracoscopic puncture wound), persistent nonpurulent effusion (88 per cent of the operative patients exhibited some serious effusion but in only 4 was it extensive or persistent enough to require special notice), probably tuberculous in origin, spontaneous pneumothorax, empyema (7 patients of whom detailed case histories are given) and contralateral spread of the disease. Less important complications seen include surgical emphysema, postoperative vomiting, injury to nerves, air embolism, pleurocutaneous fistula and dyspnea during operation.

None of these complications seemed to be due to the operation per se, particularly there seemed to be no harmful effects from the "smoke" of the galvanocautery, none of the complications seemed to emporate the original tuberculous condition, and there was only 1 death (due to valvular spontaneous pneumothorax) which was ascribable to the secondary effects of the operation of pneumonolysis.

JOHN W. BRENNAN, M.D.

Edwards, P. W., Penman, A. G., and Logan, J.: Late Results of Closed Intrapleural Pneumonolysis.
Brit M J., 1944, 2 270

In 1939 Edwards reported the immediate results of intrapleural pneumolysis on 235 patients. These patients have now been followed up for a period of five years. Bilateral operations and thorascopies without division of adhesions have been excluded from this series, which brought the number down to 200 consecutive cases of pulmonary tuberculosis treated by artificial pneumothorax, with unilateral division of the adhesions by closed intrapleural pneumolysis. When the indications existed (in 110 cases) this treatment was supplemented by phrenic avulsion. All of the patients underwent a strict course of sanatorium routine.

Of the 200 patients, 2 were lost sight of in this period, 133 (66.5 per cent) survived five years, 71 (86.5 per cent) in whom a satisfactory collapse was obtained by operation survived five years, and 56 of these were well and working after six years, none had a satisfactory collapse before operation.

A satisfactory collapse on one side seemed to greatly improve the prospect of survival in cases with bilateral cavitation.

Sputum was negative or absent three months after operation in 138 (70 per cent) of the 193 patients who were followed up. Of these sputum-negative patients, 100 (70 per cent) survived five years compared with only a 40 per cent survival in the sputum positive group. The great majority of the negative findings were confirmed by concentration and culture. The persistence of positive sputum three months after division of the adhesions indicates a poor prognosis. On the other hand a negative sputum improves the outlook in the incomplete and "ineffective" collapse groups.

Tuberculous empyema especially when secondary infection is present is a serious complication, but it accounted for only 18 per cent of the deaths in five years.

If artificial pneumothorax is employed the aim should be to obtain the most complete collapse possible by the use of intrapleural pneumolysis.

The authors have found that the collapse obtained as the result of an extensive cauterization was no less effective than that in which smaller or fewer adhesions were divided.

In those patients on whom operation carries special risk by reason of the anatomical character of the adhesions or because of the poor general condition of the subject, alternatives to artificial pneumothorax must be considered. However when contralateral disease allows of no more radical alternative the operative risk must be accepted for success in obtaining a satisfactory collapse carries with it some prospect of improvement in the contralateral disease. The abandonment of the pneumothorax without thoracoscopy and the maintenance of an unsatisfactory collapse are both bad practice.

JOSEPH K. NARAT, M.D.

Butler, E. G. B., Perry, K. M. A., and Valentine, F. C. O.: Penicillin in Acute Empyema. *Brit. M. J.*, 1944, 172.

The authors report the results of their experience in the treatment of 18 cases of acute empyema by means of aspiration and the injection of penicillin into the empyema cavity. The amount of penicillin used varied from 10,000 to 40,000 units and injections were given on alternate days.

The organisms encountered were as follows: the hemolytic streptococcus, 4 cases; nonhemolytic streptococcus, 3 cases; microaerophilic streptococcus, 1 case; anaerobic streptococcus, 1 case; pneumococcus, 7 cases; hemolytic streptococcus and pneumococcus combined, 1 case; and a mixed tuberculous and pyogenic infection, 1 case. In addition there was 1 case of traumatic hemothorax which was sterile.

The penicillin was dissolved in water so that each cubic centimeter of the solution contained 1,000 units. The smallest total amount used was 40,000 units (except in the case of sterile hemothorax, in which 30,000 units were used) and the largest total

amount used was 270,000 units. The number of aspirations and injections varied between 4 and 11.

The patients remained febrile from one week to eight weeks.

Rib resection with drainage, was done in 3 cases because of a bronchopleural fistula, both patients died. Autopsy performed on one of these patients showed empyema, pulmonary and subdiaphragmatic abscesses, fibrosis of the lung and pericarditis.

Of the 16 remaining cases, a satisfactory result was obtained in 5, that is, the patients recovered, without pleural thickening or fibrosis; in the other cases there was either a sterile effusion or more or less pleural thickening and fibrosis. The patient with mixed tuberculous and pyogenic infection became afebrile and the pyogenic organisms disappeared from the fluid.

In a summary of these cases the authors point out that the empyema cavity can be sterilized by the use of penicillin. This however is but one of the objectives in the treatment of this disease; the other is the re-expansion of the lung without fibrosis and pleural thickening, which lead to a reduced vital capacity and the risk of future pulmonary infection. Rib resection is frequently necessary to remove the large masses of fibrin that are present. Before treatment with penicillin is started the sensitivity of the organism should be determined.

FOREST D. DORRIS, M.D.

HEART AND PERICARDIUM

Cornell, A., and Shookhoff, H. B.: Actinomycosis of the Heart Simulating Rheumatic Fever. Report of 3 Cases of Cardiac Actinomycosis, with a Review of the Literature. *Arch. Int. M.* 1944, 74, 1.

Actinomycosis is the most common visceral mycotic infection in man. In about 15 per cent of the cases the infection occurs in the thorax. However in less than 1 per cent of these is there involvement of the heart.

The authors present the case of a thirty-year-old male who was seen because of cough, dyspnea, and weakness for seven months. Precordial pain had been present and severe. Examination revealed some enlargement of the heart to the left with systolic and presystolic murmurs. There was a suggestion of fluid in the right base and marked enlargement of the liver. After about six weeks of observation he became considerably worse and died from what was apparently streptococcus septicemia. Autopsy showed extensive mediastinal adhesions with obliteration of the pericardial sac. A large amount of firm pink, necrotic tissue was present and had invaded the myocardium. The posterior mediastinum was involved by the same process and an esophageal diverticulum was in the mass of scar tissue. Microscopic sections showed the typical ray fungus. The case is unusual in that the symptoms and findings suggest rheumatic fever and in that no external fistulas were present. Review of the autopsy records

In 6 additional cases of actinomycosis revealed that 2 had involvement of the heart

Analysis of these cases and of 65 others collected from the literature shows that the heart may be involved by direct extension of the infection from a neighboring organ or by metastasis through the blood. Metastatic involvement rarely produces clinical signs. About one half of the patients with involvement of the heart by direct extension have clinical manifestations. The most common clinical manifestation in cardiac actinomycosis is congestive heart failure in which the pericarditis plays a major role. The diagnosis can rarely be made clinically.

THOMAS F. THORNTON, JR., M.D.

ESOPHAGUS AND MEDIASTINUM

Collis, J. L., Humphreys, D. R., and Bond W. H.: Spontaneous Rupture of the Esophagus. *Lancet* Lond. 1944 247 179.

Spontaneous rupture of the esophagus after a heavy meal occurred in a man of forty-one years with a previous dyspeptic history. This condition should be kept in mind when doubt is felt about the diagnosis of perforated peptic ulcer. Deep emphysema in the neck is an important physical sign.

Suturing of the tear in the esophagus combined with drainage of the pleural cavity on the affected side offers the best chance of recovery.

Apart from the case reported by the authors, the diagnosis seems to have been made before death on only 3 occasions. The failure to arrive at the correct diagnosis has prevented the institution of surgical

treatment in all except 2 other cases. The present case appears to be the only one in which radical surgical treatment was given to the tear.

PAUL MERRELL, M.D.

Toreson W. F.: Secondary Carcinoma of the Esophagus as a Cause of Dysphagia. *Arch Surg* 1944 38 82.

Twenty-six cases of secondary involvement of the esophagus by cancer are analyzed. Of these 19 cases were encountered among 599 consecutive cases of cancer in which autopsy was performed; an incidence of 3.2 per cent.

Of the 26 cancers 24 were carcinomas, 1 was a lymphosarcoma, and 1 was a cancer of undetermined origin and type, probably a melanoma. The organs in which the tumors originated and the number for each were as follows: trachea or bronchus 8, stomach 7, larynx 4, breast 2, pancreas 2, testis 1, origin undetermined 1. There were 8 instances (about 30 per cent of all cases of secondary cancer of the esophagus) in which the involvement of the esophagus was definitely metastatic from a more or less distant primary tumor.

Among the 26 cases partial or complete obstruction of the esophagus with corresponding clinical symptoms was encountered in 12 cases. In 3 of these cases the involvement of the esophagus was by metastasis from a distant primary tumor.

Secondary carcinoma of the esophagus is not rare and in somewhat less than half the cases leads to more or less dysphagia.

HOWARD A. MCKNIGHT, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Nelson H.: Early Ambulation Following Section of the Anterior Abdominal Wall: An Analysis of 426 Personally Conducted Cases. *Arch. Surg.* 1944 49

Although early ambulation following intra-abdominal operations was first recommended in 1869, the practice has never been generally followed, and most of the few critically analyzed series have been published within the last two or three years.

An analysis of this series of 426 operations through 426 incisions of the anterior abdominal wall after which ambulation was practiced within seventy-two hours shows that the majority of the patients walked on the day of the operation or within the first twenty-four hours.

The incidence of immediate and delayed complications in this series was minimal. Of the 3 partial disruptions of a wound 2 occurred in patients whose wounds had been closed with catgut and for whom early ambulation had not been authorized. The third was due to an error on the part of the surgeon, who failed to order transfusions of blood and plasma for a patient who had lost a large amount of blood. Only 2 incisional hernias, both small, were observed, and there was 1 instance of recurrent incisional hernia in a patient in whom repair was inadequate. The single fatality in the series was due to cerebral thrombosis.

Good results depend on the strict observance of contraindications as well as of indications.

The advantages of the plan include the lower incidence of postoperative complications, particularly pulmonary and vascular complications; the lower incidence of nausea, vomiting and abdominal distention; the earlier return of normal function of the bladder and bowel; the maintenance of normal muscle tone; the psychological effect on the patient's morale and mental status; the acceleration of convalescence and the earlier return of working ability; the economic savings to patient and hospital.

For the reasons stated and because of its apparent absolute safety, the plan of early postoperative ambulation seems to represent a sound surgical advance and its more general employment in properly selected cases is recommended.

JOHN J. MALONEY, M.D.

GASTROINTESTINAL TRACT

De Amnesti, F., and Otis, E.: Cancer of the Region of the Cardia and of the Lower End of the Esophagus (Cáncer de la región del cardia y del extremo inferior del esófago). *Rev. med. Chile* 944, 7

In the series of cases of esophageal cancer here reported the operative technique employed in the

surgical approach to the tumor region was essentially the transthoracic method described by Churchill and Sweet (*Ann. Surg.* 1942 115: 897) and the remainder of the procedure was that described as their own method by Pack and Macner in their collective view on total gastrectomy in the *INTERNATIONAL ABSTRACT OF SURGERY* 1943 77 265. The sub-peritoneal resection of the ninth rib is preferred.

In the preoperative work, special attention is given to the diagnosis and roentgenograms are taken in all possible directions and postures of the patient (Trendelenburg) with thickened shadow media, this to be followed by esophagoscopy and biopsy. Special emphasis is placed on a diet rich in vitamins, carbohydrates and proteins and the hypochromic anemia is combated by saline and glucose solutions and transfusions of blood and plasma.

For the operation preference is given to intubation ether anesthesia variously combined with cyclopropane or nitrous oxide gas. The Levine tube is preferred to jejunostomy and is left lying for from eight to ten days postoperatively before oral feeding is started. Drop-transfusion of blood is carried on during the entire operation.

In the authors' service at the Hospital del Salvador 6 transthoracic explorations have been carried out, with 3 patients limited to simple exploration (no deaths). Of the 3 persons in whom removal of the tumor was decided on 1 died on the ninth day after operation and the remaining 2 have now survived the operation for two and a half months. In 1 instance the spleen was removed with the stomach.

Complete case histories of the 6 patients, all of whom were forty-five years of age or over are appended.

JOSE W. BARRERA, M.D.

Ingelfinger, F. J.: Medical Progress: The Late Effects of Total and Subtotal Gastrectomy. *S. Engl. and J. M.* 944 331 332

Gastrectomy is being performed with ever increasing frequency not only for gastric neoplasms but also in the treatment of peptic ulcers of the stomach, duodenum and jejunum. The reason for this is that resection of the human stomach, particularly of the distal half, has become a practical surgical procedure that carries a remarkably low mortality rate.

In cases of cancer gastrectomy may have to be most extensive, sometimes total. In cases of ulcer the amount of stomach removed varies with the particular problem involved in each instance. Many surgeons recommend the removal of the gastric antrum and at least two-thirds of the stomach, under the reasonable conviction that the chances of a recurrent ulcer are decreased by leaving a gastric remnant that has little or no capacity to form free hydrochloric acid. Indeed the suppression of the normal secretory functions of the stomach is one of the purposes in undertaking a gastrectomy for ulcer.

The question is often asked: Can man live without a stomach or with a stomach whose functions are grossly impaired? The answer is: Yes, but life under such conditions is not invariably normal. The author considers recent evidence bearing on this problem. The present popularity of gastrectomy warrants an appraisal of any possible late effects that may follow total or subtotal removal of the stomach. The immediate postoperative complications are not discussed. So far as possible the author reviews only those effects that can be directly traced to resection of gastric tissue. He asserts that in all probability some of the symptoms for which gastrectomy has been blamed have actually been caused by postoperative ulcer, gastritis or jejunitis. In general he says: "The consequences of removing portions of the human stomach depend on the nature of the primary disease, the extent of the resection, the surgeon's skill and various factors that vary with the patient's age, diet and mental attitude." The majority of the gastrectomy patients find their mode of life unchanged by the fact that half or more of the stomach has been removed.

Certain clinical observations, however, have been noted in the cases of patients who have undergone subtotal or total gastrectomy. About 30 per cent of the patients do not regain their normal weight and some do not regain their preoperative weight. Following subtotal or total gastrectomy about 10 per cent of the patients have an incidence of a persistent postprandial syndrome which follows a fairly typical pattern soon after taking a meal, particularly if the meal is large. There is marked epigastric pressure, distention and fullness. Nausea may accompany these symptoms and occasionally weakness, dizziness, perspiration and palpitation occur within an hour after the meal. In general failure to gain weight is particularly noticeable in the group of patients complaining of gastrointestinal symptoms, but the converse does not hold. Many underweight patients are completely symptom free.

Diarrhea with cramps has been reported as a sequel to gastrectomy, but it is rather rare. Many patients, however, have soft stools following the operation.

Many writers emphasize the fact that the symptoms that can be ascribed to total or subtotal gastrectomy tend to decrease in frequency and intensity as the interval between the operation and the follow-up observations lengthens. Much of the distress present during the first postoperative year tends to disappear subsequently. This improvement is brought about partly by the patient's realization that he must avoid large meals and that he can get along comfortably on six small meals a day. An equally important cause for improvement, however, is the capacity of the gastrointestinal tract to adjust itself to new conditions.

Following subtotal gastrectomy a considerable derangement in gastrointestinal motility ensues. Fluoroscopic observations show that in some instances material leaves the gastric remnant with

difficulty but much more frequently the contrast medium enters the intestine with such rapidity that the term dumping stomach has been used under these conditions. Many modifications of the method of gastric resection have been proposed with a view to lessening subsequent motor disorders. In the European literature a considerable argument has developed concerning the relative advantages of the Billroth I and the Billroth II operations. As yet no conclusive evidence has been presented that one type of operation alters normal gastrointestinal motility less than does another. The gastrointestinal tract makes functional adjustments irrespective of the initial surgery and other factors besides the exact size and position of the stoma influence the rate of gastric evacuation. The gastric remnant, which is at first small, gradually enlarges and resumes some of the reservoir function of the stomach. If the gastric remnant is extremely small, the small bowel dilates to form reservoirs near the anastomosis. The partially resected stomach sometimes exhibits peristaltic waves, but in other cases peristalsis is not seen and the general motility pattern tends to be abnormal. Some investigators, notably Ravdin and his associates, have ascertained that hypoproteinemia is a factor in the retardation of gastric emptying after gastrectomy. Undoubtedly hypoproteinemia can exert a marked influence on motility, but other factors are at work as indicated by the studies of Chauncey and Gray, who could not correlate the level of the serum proteins and the rate of gastric emptying through a stoma. Even if the stoma is anatomically perfect, gastric evacuation after subtotal resection may be delayed by functional disorders. The effect of certain foods on the motility of the upper gastrointestinal tract illustrates the role played by pressure gradients. When fats, hydrochloric acid, or hypertonic solutions enter the intestinal loops distal to the anastomosis, the resected as well as the normal stomach exhibits delayed emptying. It is now known that this delay is produced by relaxation of the gastric musculature, not by sphincteric contraction.

The incidence of functional disorders of gastrointestinal motility after gastrectomy is hard to compute. In the first few months after operation such disorders are doubtless quite prevalent and they as well as mechanical stomal defects should be considered as possible causes of improper gastric evacuation after partial gastrectomy. The edema of hypoproteinemia, if present, may partially occlude the stoma, but it also produces a serious derangement of all gastrointestinal motor functions. With the aid of proper dietary management, functional disorders tend to subside during the first postoperative year and subsequently they are encountered infrequently.

The effects of gastrectomy on absorption have been carefully studied. In gastrectomized patients the glucose tolerance test shows a rapid rise in blood sugar followed by a fall that may reach hypoglycemic levels. In a few cases symptoms occur during the hypoglycemic phase. Carbohydrates and pro-

teins are usually adequately absorbed but some impairment in the absorption of fats may occur.

Pernicious anemia is an extremely rare sequela of gastrectomy. It is quite possible that some of the cases of pernicious anemia associated with gastrectomy are merely due to coincidence. A normochromic or hypochromic type of anemia, however, is not infrequent among patients with gastrectomies.

In general, the outlook following gastrectomy is favorable. A nourishing diet, taken frequently in small quantities and fortified with vitamins and iron often alleviates some of the complications of gastrectomy. Symptoms and various motility disorders, which may be prominent during the first postoperative year subsequently tend to correct themselves spontaneously. Even when the undesirable sequelae of gastrectomy are marked they rarely interfere with the patient's ability to work, and practically never are they so dangerous or distressing as the disease for which the gastric resection was undertaken. Hence the fact that these sequelae may occur can not be considered in any sense as a contraindication to gastrectomy in adults. In the rare cases in which resection has to be considered in an adolescent, it may be wise to limit the extent of the resection.

MATTHIAS J. SEIFERT, M.D.

Hanno, H. A., and Menah M.: Leiomyoma of the Jejunum; Intermittent Melena of Fourteen Years' Duration; and Fatal Hemorrhage. *Ann Surg* 1944 120 99.

The incidence, pathology and clinical features of leiomyoma of the small intestines are reviewed.

The case of a patient with a leiomyoma of the jejunum, who had no known episodes of melena over a fourteen year period and a fatal hemorrhage is reported. It is of interest that ulcer disease, although suspected had never been demonstrated conclusively and that a gastroenterostomy had been injudiciously performed. In all likelihood, had the presence of a tumor of the small bowel been strongly considered and appropriate surgical exploration advocated, the patient might not have died.

This case emphasizes the fact that the presence of small intestinal neoplasms is much too infrequently suspected. The diagnosis of tumors of the small bowel both benign and malignant rests upon a high index of suspicion. The possibility of a neoplasm of the small intestine should be considered in any patient who has repeated episodes of melena in the absence of any demonstrable lesion in the upper gastrointestinal tract or colon, and in any patient with repeated episodes of partial or complete obstruction in the small bowel. In such instances, despite the absence of roentgenological demonstration of a lesion, celiotomy is indicated. Since the ratio of benign to malignant tumors is much greater in the small intestine than in other parts of the gastrointestinal tract, surgery for tumors of the small bowel should on the whole afford a better ultimate result than can be expected for tumors of the esophagus, stomach or colon. CHARLES BAXON, M.D.

Rosin, I. R.: Chronic Bilharzial Appendicitis. *Ca Proc.*, 1944, 3 906.

A brief description of the pathology, history and clinical features of chronic bilharzial appendicitis is given. Although there is still considerable difference of opinion as to whether or not a true chronic appendicitis per se exists from this series it is clear that the pathological entity of chronic bilharzial appendicitis is definitely established and must be borne in mind in the greater part of the entire African continent. Definitely substantiated illustrative cases falling into four different groups are described. These illustrative cases were chosen from 64 cases of definitely established bilharziasis in appendices removed during the past five years. The interesting fact that the urinary infecting agent bacillus haematobium was always recovered from the digested tissues was stressed. The importance of environment in cases of vague abdominal dyspepsia was noted. The overwhelming importance of a routine full histological examination of all appendices removed in the greater part of Southern and Central Africa is strongly urged. All bilharzial cases should be followed up with routine intravenous antimony therapy.

Interesting photomicrographs illustrating the different types of lesions found and described in this series of cases are given. CHARLES BAXON, M.D.

Kaufman, L. R., and Merabheimer, W. L.: Sulfonamides in Appendicitis. A Review of 412 Consecutive Cases and an Analysis of Fatalities. *J Surg* 1944, 65 393.

The oral and parenteral administration of sulfanilamide has been rapidly supplanted by the intraperitoneal application for the more advanced forms of appendicitis. With the intraperitoneal administration the incidence of complications was lower than when only oral and parenteral routes were utilized. Similarly the mortality rate was lower when the sulfonamides were employed intraperitoneally.

The mortality rate is better when no drainage is used. Drainage, however, is indicated when a localized abscess is present, but it adds to the hazard when there is a generalized peritonitis. Again in favor of intraperitoneal sulfonamides is a shorter number of hospital days.

There is apparently little danger of the formation of adhesions from the intraperitoneal application of sulfanilamide powder. However sulfathiazole powder may be a contributing factor according to several observers. Also wound healing may be delayed by sulfathiazole, but not by sulfanilamide.

It is obvious that many factors have contributed an important share to the reduction of the mortality. Among these is the intravenous use of chlorides, plasma or blood to establish optimum fluid balance and the routine use of the McBurney incision, of oxygen, the Wagenseen or Furness suction and the efficient use of the Miller Abbott tube. Since these factors have been brought into play the mortality rate has been reduced. HOWARD A. MCKINNEY, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Walters, W. Watkins, C. H. Butt II R., and Marshall, J. M. Amebic Abscess of the Liver Un-
suspected until Perforation. *J Am M Ass*
1944, 125 963

The authors report 2 cases of unsuspected amebic abscess of the liver which were asymptomatic until sudden perforation of the abscess to the right sub-diaphragmatic region took place. Both patients had been returned to the mainland from naval duty in the South Pacific islands because of a diagnosis of filariasis and lymphadenitis. In neither case was diarrhea present nor were amebae found in the stools. A diagnosis of amebic abscess of the liver was made only after perforation of the abscess to the sub-diaphragmatic region. The similarity of symptoms in both cases was striking after perforation of the abscess occurred. These symptoms were characteristic of amebic abscess of the liver namely chills and fever, lower thoracic and upper abdominal pain, loss of weight and weakness, enlargement of the liver and abdominal tenderness together with a pronounced leucocytosis. There was a sudden development of aching pain in the right shoulder in the right costovertebral region and lower portion of the right thorax which extended to the abdomen with muscle spasm in the right upper quadrant. Roentgenological examinations of the thorax revealed no evidence of pneumonia but showed a progressive elevation of the right half of the diaphragm with an irregular dome-shaped bulge and an increase of the acute cardiophrenic angle to a right angle. There was a variation in temperature daily in both cases of approximately 4° F. In one of these patients the pulse rate increased to a maximum of 140 beats per minute on the day of operation. As a rule the finding of endamoeba histolytica in the stools clinches the diagnosis, however this organism was absent from the stools of both of these patients.

In case 1 the general condition of the patient improved after the administration of emetine 3 gr (0.3 gm.) of emetine hydrochloride were given on the first day 2 gr (0.2 gm.) on the second day and 1 gr (0.065 gm.) on the following four days until a total of 9 gr (0.6 gm.) was administered. Two days following the institution of emetine therapy the patient's temperature returned to normal and varied from 97.5° to 99°F for twelve days. During this time, however the right half of the diaphragm continued to rise progressively because, as was afterward determined, of the increase in size of the sub-diaphragmatic abscess. Open operation was performed and revealed an abscess cavity 10 cm. in diameter in the right lobe of the liver with an opening 3 cm. in diameter into the sub-diaphragmatic abscess cavity. Both cavities contained approximately 1,000 cc. of yellowish white thick, purulent debris with clots of fibrin. Smear and culture showed gram-positive cocci. A strip of iodoform gauze impregnated with sulfanilamide powder was placed in the cavity of

the liver and Penrose drains were placed in the sub-diaphragmatic abscess cavity. Healing occurred in a few days and was followed by complete recovery.

In case 2 there was no apparent response to emetine which had been given at the rate of 1 gr (0.065 gm.) per day on three consecutive days. Since roentgenograms showed a steady increase in the elevation of the right side of the diaphragm a diagnosis of hepatic abscess of unknown origin was made. In view of the extremely serious condition of the patient, the progressive increase in the pulse rate to 140 beats per minute and the temperature of 103.5° F. operation seemed advisable even though there was the possibility of an amebic abscess of the liver with perforation. Surgical drainage was performed as an emergency procedure. A sub-diaphragmatic abscess containing about 240 cc. of typical amebic material was drained through a right sub-costal incision. An abscess cavity approximately 12.5 cm. in diameter was found in the right lobe of the liver by needle aspiration. This cavity was opened and from 500 to 700 cc. of creamy white pus with fibrin and cellular debris were drained out. Smear and culture revealed the endamoeba histolytica. A strip of iodoform gauze impregnated with 5 gm. of sulfanilamide was inserted into the abscess cavity within the liver. This was removed on the twelfth postoperative day after repeated daily soakings with 1:5,000 solution of potassium permanganate. Penrose drains were placed in the sub-diaphragmatic abscess. Complete recovery followed.

Reports such as these lead one to believe that amebiasis is a much more frequent disease than has been commonly supposed. While it is endemic in many portions of the United States and present in all sections the present worldwide dispersal of our armed forces and their subsequent return home will bring about an increasing frequency of this disease. The percentage of cases of amebiasis in which amebic hepatitis or abscess develops is unknown. The avoidance of these developments depends on several factors chief of which are prompt recognition and thorough treatment of the amebiasis. It seems reasonable to suppose that under ideal conditions and if all patients with fresh infections of endamoeba histolytica are promptly and thoroughly treated amebic disease of the liver would not occur since hepatic involvement is always a secondary complication to the disease in the colon. This statement does not mean that every patient who has amebic disease of the liver has a diarrhea or even that he has had diarrhea. It is apparent that many amebic infections of the colon are largely asymptomatic.

MATTHEW J. SWEET, M.D.

Kennaway E. L.: Cancer of the Liver in the Negro in Africa and in America. *Cancer Res* 1944, 4 572

The author has examined the incidence of primary carcinomas of the liver in the negro in Africa comparing it with the incidence of the same lesion in the negro in the United States. He concludes that such

data as are available suggest that the very high incidence of primary cancer of the liver found among negroes in Africa does not appear among negroes in the United States and is, therefore, not of purely racial character. The prevalence of this form of cancer in Africa may be due to some as yet unidentified extrinsic factor. The statistical evidence concerning this question is confused by the inclusion of cancer of the gall bladder in the same category with cancer of the liver.

EARL O. LATIMER, M.D.

Johnson, W., Majstrom, B. L., and Volk, B. W.: A Clinicopathological Study of 100 Cases of Acute and Chronic Gall Bladder Disease. *Ann. Int. M.* 944 31 43.

A study is reported of the case histories of 100 patients who have been operated upon during the last ten years. Calculi were present in 71 patients. Cholecystography showed accurate diagnosis in over 90 per cent of the cases. Among the noncalculous cases, 13 of the patients reported permanent relief, 3 had only temporary relief, and 4 were made worse by the operation. The authors conclude that noncalculous cholecystitis is best treated medically, but when such treatment fails to bring adequate relief cholecystectomy is recommended. In the calculous type surgery is best.

WALTER H. NADLER, M.D.

MISCELLANEOUS

Bulge, R. E.: Experimental Observations on the Human Ileocecal Valve. *Surgery* 944, 6 356.

The authors had the opportunity to make experimental observations on the human ileocecal valve of a twenty-six year-old woman. Their observations were made two months after the exteriorization procedure during a period of four weeks prior to a right hemicolectomy.

The cecum was open, and was attached to the abdominal wall in such a fashion as not to permit encroachment of the parietes upon the terminal ileum or the ileocecal valve. Approximately 10 cm. from the valve the lower ileum was exteriorized and completely cut across so that all intestinal content was evacuated through a proximal external ileal fistula. No intestinal content was transported by way of the distal ileal loop into the cecum.

Qualitative and quantitative control studies of spontaneous activity of the extramural terminal ileum, the sphincter and ileocecal valve were recorded during twenty periods of from thirty to one hundred and twenty minutes each. Additional control records were obtained between the drug experiments.

Control records revealed that there were periods of quiescence and activity in all three areas. The activity of the segments varied, but at times all the segments were quiet. During periods of motility the proximal exteriorized small-bowel loops were equally and similarly active, and expelled intestinal content. At no time was there spontaneous activity in the ileocecal lips, the sphincter or the extramural termi-

nal ileum, independent of activity in the preterminal ileal loops. The extent and frequency of contractions varied, the contractions being most energetic in the morning and less active in the evening. Propulsive activity constituted a small fraction (10 per cent) of the total motility which was nonpropulsive, with varying states of tone. During evacuation at the proximal fistula (usually from two to three hours after a meal) a short comparable period of sphincter and valve motility occurred, which was followed by relaxation of the entire intracecal portion of the terminal ileum.

It was observed that retraction or shortening of the ileocecal structure occurs when the segments are co-ordinated to accept a propulsive wave from an adjacent segment. A nonpropulsive or segmental wave is not associated with shortening of the active segment and the valve is not obliterated.

The author's experimental results indicate that the mechanical, hormonal, and local reflexes of the ileocecal valve and sphincter are so adjusted as constantly to produce responses identical with those of the small intestine to adrenergic and cholinergic drugs. The balloon method of investigation failed to reveal any fundamental distinctions in the behavior of the ileocecal valve, the ileocecal sphincter and the small intestine. The presence of an area of increased contractility was observed within the cecal portion of the terminal ileum. Prolonged tonic contractions, characteristic of sphincter action, were not observed.

JOSEPH K. NARAZ, M.D.

Whitehouse, F. R., and MacMillan, A. M.: Visualization of Rubber Tip of Gastroscope; Differentiation from Gastric Ulcer. *Gastroenterology* 1944 3 23.

The rubber tip of the gastroscope can simulate gastric ulceration.

It is recommended that the rubber tip be colored green or another easily identifiable color to prevent this mistake.

CHARLES BARON, M.D.

Co Tul Wright, A. M., Mulholland, J. H., Canabba, V., and Others: Studies on Surgical Convalescence. Sources of Nitrogen Loss after Gastrectomy and the Effect of High Amino-Acid and High Caloric Intake on Convalescence. *Ann. Surg.* 1944, 30 99.

In a preliminary communication on the subject of surgical convalescence it was reported that patients convalescing from gastrectomy when fed with a high caloric and high amino-acid diet (nutramigen) were able to maintain a consistently positive nitrogen balance throughout the postoperative period, to gain weight, and to achieve an early return to strength, with a significantly shortened convalescence. This was in striking contrast to the response of a similar group of patients under the classical postoperative ward regimen who had a consistently negative nitrogen balance, a loss of body weight, a longer period of postoperative debility and a more prolonged stay in bed.

In the present series of 19 cases, 8 patients were on routine ward regimen, 8 were fed high caloric and high amino-acid mixtures and 3 were fed insufficient quantities to maintain the nitrogen equilibrium.

In the series under the classical ward regimen there was a consistent nitrogen deficit and loss of weight, and a necessarily prolonged stay in bed. Objective ergography showed postoperative asthenia which had not disappeared even on the twelfth postoperative day. In the series of patients who were fed with high caloric and high amino-acid mixtures, there was a consistent nitrogen surplus, a steady gain in weight, and a stay in bed of less than one half that of the control series. The ergograph showed an early return of endurance, on from the fifth to the sixth postoperative day to above that of the initial reading. These findings confirm the results of the preliminary report.

The principal cause of nitrogen loss in postgastrectomy convalescence is the starvation postoperative regimen. Whether there was a larger excretion of urinary nitrogen in the patients in the control group than was present preoperatively is not known.

A hyperalimentation regimen is therefore recommended in routine cases of gastrectomy in order to prevent nitrogen loss, shorten convalescence, and prevent postoperative asthenia.

While the complications in the hyperalimmented group were fewer and less severe than those in the control group, the present series is too small to allow statistically significant conclusions to be drawn from it.

SAMUEL KAHN, M.D.

Presno Albarran, J. A.: Contribution to the Subject of Lumbar Hernia (Contribución al estudio de la hernia lumbar). *Rev. med. ciruj. Habana* 1944 49 53.

No definite operative procedures have been established for the ruptures through the upper lumbar

region as described by Grynfeldt although such hernial predisposition is now generally recognized as being more frequent than that for Petit's triangle; therefore, an operative technique is proposed by this author.

This operation consists essentially in turning for ward as a flap the aponeurosis of this region (through which the hernial sac is passing) tying off and incising the sac, and then sewing the cut edge of the remaining unturned part of the lumbar fascia forward to the base of the flap along the so-called ligament of Henle with mattress sutures; thus the quadrilateral of Grynfeldt is completely closed off. Finally the flap of the aponeurosis of the transversus abdominis is turned back in double-breasted coat fashion and sutured to the fascia covering the erector trunci muscles.

Albarran reports 3 hernias, all of the Grynfeldt type, on one of which he successfully performed his operation. All these hernias occurred in adult males, sixty-four, sixty-two and seventy years old, respectively, all of them were of the acquired type, 2 on the left side, 1 on the right, and all occurred in individuals presumably injured to heavy labor. In no instance was the sac very large or the condition very annoying (2 individuals refused operation). In 1 case the presence in the sac of hollow viscera was evident and the x-rays disclosed an out-sacculution of the colon at the level of the hernial egress.

Incidentally the author reports 2 other cases of hernia at the Garcia Calixta hospital in Havana, which were eventually operated upon successfully by other physicians: one was on a congenital basis in a female infant of seven and one-half months; the other in a white male seventy years of age and had been diagnosed as tuberculous peritonitis. The hernia in this case had been mistaken for a cold abscess (incision, fecal fistula).

GYNECOLOGY

UTERUS

Bickera, W.: A Study of the Endometrial Pattern Before and After Treatment for Amenorrhoea. *Am. J. Obst.*, 1944, 48, 58.

This study is based on the observations made upon 9 women whose chief complaint was secondary amenorrhoea. The term secondary amenorrhoea was limited to those patients in whom there had been a cessation of menses for a period of five months or more. The patients with amenorrhoea are divided into two groups according to the endometrial pattern which the patients show.

Repeated endometrial biopsies are taken at weekly intervals to establish the endometrial type.

When a persistent proliferative phase of endometrium is found at successive weekly biopsies this indicates a failure of ovulation and, therefore, a pituitary-ovarian defect. The finding of a persistent secretory endometrium at successive biopsies suggests the influence of a persistent corpus luteum.

Seven of the 9 patients had a persistent proliferative phase (anovulatory) endometrium. The endometrium varied from a very atrophic type with scarcely any glandular structure to marked hyperplasia. Although the 7 amenorrhoeic patients showed a wide variation of endometrial pattern, the pattern in any 1 case was extremely constant.

When weekly biopsies were taken of these patients it was found that there was an amazing persistence of the endometrial pattern in each individual patient.

The pathological physiology involved in anovular amenorrhoea is thought to be the result of a pituitary ovarian failure primary or secondary to some systemic disease.

Treatment consisted in the stimulation of uterine bleeding by the sudden withdrawal of estrogen progestosterone to a lower level in an attempt to simulate the normal physiology of the body and thus induce normal uterine bleeding. After the patients had been adequately studied by means of successive biopsies they were given stilbestrol, 5 mgm. daily at bedtime for ten nights. On the last five days of the stilbestrol therapy, it was supplemented by progestosterone, 5 mgm. daily given intramuscularly. Following this intensive ten-day therapy, uterine bleeding occurred in 6 of the 7 patients within four days. The average duration of the induced menstruation was three and one-half days. One patient with marked atrophy of the endometrium failed to menstruate. In the 6 successful patients the ten-day course of treatment was repeated on the fifteenth day from the first day of the induced bleeding. Five of the 6 patients had another episode of uterine bleeding within fifteen days after completing the second course of therapy. No further treatment was given. Of the 5 patients in whom a second bleeding phase was induced all continued to menstruate at fairly regular

intervals for periods of seven, three, twelve, one, and twelve months, respectively without further treatment. Of these, 3 lapsed into their original amenorrhoeic state when treatment was stopped, but only after three and nine months of spontaneous menstruation respectively.

Two of the 9 amenorrhoeic patients were found to have a persistent secretory phase endometrium.

Case No. 8 showed no pelvic pathology and the ovaries were normal to palpation. Endometrial biopsy showed a persistent secretory phase. Despite a negative pelvis, the diagnosis of persistent corpus luteum was made and a laparotomy performed. At the operating table the ovaries were smooth and of normal size, with no follicle cysts. Incision depicts the right ovary exposed a healthy glistening yellow corpus luteum approximately 1 cm. in diameter. This was excised and menstruation followed on the second day and recurred at from twenty-seven to thirty-one-day intervals until the patient became pregnant, after a six year sterility.

Case No. 9 was treated as a sterility study and menstruation ceased for three months. The Friedman test was positive. The patient was followed for two more months, during which time the amenorrhoea persisted but the uterus did not enlarge. A soft doughy mass was palpable in the region of the left ovary. It was estimated to be 9 cm. in diameter. Repeated endometrial biopsies revealed a persistent secretory phase of endometrium. The patient was operated on and a corpus-luteum cyst of the left ovary 6 cm. in diameter was removed. Thorough curettage failed to reveal chorionic villi. The patient menstruated normally on the third postoperative day and a normal cycle has occurred since.

HENRY C. FALK, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Lesh, R. E.: Torsion of Ovarian Cysts in Children. *Am. J. Obst.*, 1944, 47, 845.

Torsion of ovarian cysts in young children is a rare occurrence. The author reports 2 cases: one a simple cyst in a child of four and the second a dermoid in a twelve-year-old girl. It is suggested that the presence of a cyst be considered in any child complaining of abdominal pain. Surgical removal is indicated.

J. ROBERT WILLIAMS, M.D.

Schwartz, F. L.: Salpingitis and Tubal Patency. *Am. J. Surg.*, 1944, 64, 65.

In determining tubal patency hysterosalpingography when properly done even in the presence of salpingitis, carries no more risk than any other diagnostic procedure. While it may lead to more possible complications, the morbidity is negligible, and the procedure is superior to gas insufflation from both diagnostic and therapeutic standpoints.

In the presence of salpingitis of sufficient duration and severity to warrant surgery but in cases in which preservation of child bearing function is desired this procedure is of value for deciding between continued local treatment and surgery.

A series of 165 patients was reviewed. The roentgenographic findings were compared with the surgical and pathological pictures. There were 12 pregnant patients and 18 on whom bilateral salpingectomy was done. In all those coming to surgery, definite tissue changes were found and all patients were free from symptoms after surgery.

Salpingitis may be present even though a tube is permeable. Such tubes present certain characteristic roentgenological features such as elongation, clubbing and redundancy at the extremity as well as areas of stenosis and dilation. Pregnancy is rare in this type of tube in spite of its permeability.

Occlusion at the cornu prevents reinfection from below and, as a general rule, results in self-sterilization and healing of the tubes.

There were 29 women with both tubes completely patent who had entirely negative histories and findings. Disturbances of ovulation were quite frequent and there was only 1 pregnancy in the group.

Seventy four patients had both tubes patent but some history of salpingitis. In this group the tubes were listed as patent provided they were permeable to oil even though there was evidence of partial obstruction. From serial films it appeared that many of these tubes had been opened by pressure of the oil. Nine of these patients became pregnant and 7 were subjected to surgery.

Of 5 patients with one tube patent and the other blocked at the cornu and with negative histories and findings 2 became pregnant.

Twenty-one women had one tube blocked at the cornu with symptoms on the patent side. There were no pregnancies and 7 women required surgery.

With one tube blocked at the cornu 4 patients had bilateral symptoms and 1 patient presented symptoms on the same side. One patient had one tube patent and the other blocked at the isthmus following removal of a large ovarian cyst.

Five women had one tube blocked at the fimbriated extremity 1 of these required surgery.

Of 11 patients with both tubes blocked at the cornu 10 were well and one was well after operation.

Two patients had both tubes blocked at the isthmus. One had a bilateral hemisalpingectomy previously and is well the other had mild recurrent salpingitis.

Eight women had one tube blocked at the cornu and the other blocked at the fimbriated extremity.

Five were free from symptoms and 2 of the 3 with symptoms required operation.

Four patients had both tubes blocked at the fimbriated extremities 3 are well and the fourth had a bilateral salpingectomy.

The not infrequent roentgenological findings of tubal damage in young women with completely negative histories and tubal findings suggests the possibility that the vague lower abdominal pains often complained of during childhood and adolescence may be the result of an unrecognized blood or lymph borne salpingitis.

In a number of cases with a record of previous varied treatments symptoms have been relieved by hysterosalpingography.

Tubal patency can be and often is coincidental with salpingitis, although in the majority of such cases the tubes are not completely patent. Cornual occlusion usually results in self-sterilization and self healing.

CHARLES BARON, M.D.

MISCELLANEOUS

Finkler, R. S. Zondek's Simplified Treatment of Secondary Amenorrhea. *Am J Obst* 1944 48: 26.

A series of 31 patients with secondary amenorrhea due to pituitary or ovarian deficiency is presented and the results with the simplified two-day treatment are described.

This method devised by Zondek consists of the injection of a combination of estradiol benzoate (2.5 mgm.) and progesterone (12.5 mgm.) on two consecutive days. Uterine bleeding was produced in 25 patients (80.6 per cent). Among the 6 patients who did not react were 4 with marked uterine hypoplasia. In 2 of the unresponsive patients the amenorrhea had persisted for more than two years. By restricting the simplified treatment plan to patients with an amenorrhea of less than two years duration the percentage of favorable responses can probably be further increased. No marked changes were produced in the endometrial pattern with the two-day treatment as evidenced by the pre- and postmedication biopsy specimens.

The advantages of the simplified method are discussed. The two-day treatment plan should be employed in all those instances of functional amenorrhea of less than two years duration in which thyroid medication has failed to yield results, and in which for some reason or another it is desirable or imperative to obtain uterine bleeding in as short a period of time as possible.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Sontag, L. W. Reynolds, E. L., and Torbet, V.: The Relation of Basal Metabolic Gain During Pregnancy to Nonpregnant Basal Metabolism. *Am. J. Obst.* 1944 48 315

The explanation of the changes in the metabolism during pregnancy may lie in the effect of the fetal thyroid on the hypothyroid mother. It is possible that the physiological changes of pregnancy provide a resurgence of function of the maternal thyroid. In the Fels nonpregnant series, 44.8 per cent of the women had basal metabolic rates below 10 per cent on the basis of the Mayo Clinic standards. Basal metabolic rates during the ninth month of pregnancy were preponderantly at the level which would usually be considered normal for nonpregnant women. These facts can probably be explained on the basis of differences in the conditions under which the basal metabolism is measured. The low basal metabolic rates observed in the Fels series were compared with Davis Milwaukee and Wilmington series which also showed low values. The possible need for interpretation of test results in terms of the environment, the significance which the patient attaches to the test, the general anxiety and the previous test experience is suggested.

EDWARD L. CORNELL, M.D.

Didle, A. W.: The Effect of Travel on the Incidence of Abortion. *Am. J. Obst.*, 1944, 48 354.

Ninety-eight and one-tenth per cent (1,038 cases) of the patients considered were under observation to the end of the third month of pregnancy, while 91.5 per cent (968 cases) were followed up beyond the fourth month. All of the abortions seen occurred before the end of the third month with the exception of 8.

During the period of scientific scrutiny a diagnosis of abortion was made and proved anatomically 123 times, or an incidence of 11.6 per cent. Three individuals were seen through 2 each. Of the 123 23 were dropped from the study because there was no information on travel. In the final analysis, there were 239 travelers and 467 "nonjourney" women for the first sixteen weeks under study.

Among the 446 women with complete data, 215 took no trips 179 traveled from 70 to 6,000 miles each in a continuous tour by bus and/or car and/or train before the end of the fourth month and 53 covered from 170 to 4,000 miles each after this period of time. Repeated trips averaging 1,000 miles were again made by 30 of the 179 patients after the fourth month. The distribution by state, age of the patients, blood counts and body weights were approximately equal for the different groups. The abortions predominated in the second month (51 cases) with 41 in the third, and 8 in the fourth.

Consideration may now be given to the problem of travel and abortion. Of the 239 travelers who toured before the end of the fourth month, 16 (6.6 per cent) had untimely births as contrasted to 11 (17.9 per cent) among the control or sedentary series. Among the 179 protocols for which the distances covered were known definitely 46 (25.7 per cent) of the women were multigravidae and 37 (20.6 per cent) parous. These figures correspond favorably with the percentages for the entire clientele. Of the 16 "journey" women having abortion difficulties, 7 were parous and 1 other was gravid previously. The remaining 8 were primigravidae.

Up to the present time, statements have been made in the literature cautioning pregnant patients against travel, but in so far as clinical data are concerned, material to substantiate these cautions is all.

Formerly when women became pregnant, the majority stayed near home and abstained from taking extended trips. As a result, no one physician or clinic had the opportunity of reviewing the results of travel on the incidence of abortion in a relatively large number of cases. Today the means of transportation are so modernized that they do not lead themselves well to the evaluation of the abnormalities, if any produced by rough riding.

EDWARD L. CORNELL, M.D.

LABOR AND ITS COMPLICATIONS

Roberts, P. G.: The Use of Methergine (Syntetic Ergonovine) in the Third Stage of Labor. *Bull. J. Surg.* 1944, 52 380.

Kirchhof and others of the University of Oregon, Department of Pharmacology studied the oxytocic activity of methergine on the uterus and on the sympathetic nervous system. Their experiments showed that, in the guinea pig or the rabbit, methergine was equal or superior to ergonovine in activity. Fetal toxicity could not be demonstrated in small animals in the doses employed.

Stoll and Hofmann described methergine as α -hydroxy acid- β -hydroxybutylamide. Methergine was administered intravenously in doses of 1 cc. containing 0.5 mgm. of lysergic acid- β -hydroxybutylamide-2 to 34 patients (6 primiparas and 28 multiparas) in the third stage of labor. Immediately after delivery of the infant a 1 cc. ampule of methergine was given intravenously. With the first change of the uterus to firmness (usually within from twenty to thirty seconds) expression of the placenta was attempted. Spontaneous expulsion into the vagina was a common occurrence. Expression was usually accomplished by compression of the anterior and posterior surfaces of the uterus without downward pressure of that organ into the pelvis.

The method for measuring blood loss was as follows:

Immediately after delivery of the baby an oil-silk drape was placed under the buttocks of the patient and a fresh pan was placed on the floor. In cases in which episiotomies were done the drape was pinned to the perineum above the incision to form a trough for the reception of uterine blood which was measured carefully.

The average loss of blood in the patients who had received methergine was 181 cc. and the average loss in the control series was 247 cc. A blood loss of less than 500 cc. occurred in 93 per cent of the women who had received methergine a very favorable figure compared with 75 per cent of the control series. A severe hemorrhage of 850 cc. of blood occurred in 1 case (2.94 per cent of the patients) in which the drug had been given but the greatest corresponding loss in the control series was 1,200 cc. (7.66 per cent).

Certain factors are of utmost importance for the reduction of blood loss when an oxytocic preparation is used intravenously in the third stage of labor viz.

1. Immediate uterine massage after the drug is injected—from twenty to thirty seconds.

2. Immediate expression of the placenta as soon as the first contraction is felt after intravenous injection. The operator must keep his hand constantly on the fundus in order to detect that contraction.

A marked shortening of the third stage of labor was characteristic of the cases receiving methergine. The response to natural ergonovine was weak in comparison with the rocklike firmness of the fundus after the administration of methergine. Furthermore this hard contraction was maintained for a long period of time.

In cases of cesarean section, the surface of the uterus becomes mottled with paler and darker areas the entire fundus shrinks in size and bleeding becomes minimal. After this reaction has been observed it is not surprising that in the normal delivery there is prompt separation of the placenta with almost complete cessation of bleeding.

In 83 per cent of the patients receiving methergine the third stage of labor lasted five minutes or less. It is the author's belief that if the placenta has not been delivered within twenty minutes after the intravenous administration of an ergonovine preparation it should be considered a retained placenta and steps taken to deliver it by manual extraction should a contraction ring be forming.

The reaction time averaged thirty seconds, although in many cases it was only ten seconds. The fundus remained in a remarkably hard state for several hours. In all cases, contraction of the fundus following the administration of methergine was stronger and of considerably greater intensity and duration than with the usual ergonovine preparations. If there is much delay between the time of drug administration and the attempt at placental expression the incidence of lower uterine contraction ring with the danger of retention of the placenta is increased.

In both the methergine group and the control group there was 1 case of partially retained placenta.

DANIEL G. MORTON, M.D.

Mendelson C. L.: The Management of Delivery in Pregnancy Complicated by Serious Rheumatic Heart Disease. *Am. J. Obst.* 1944 48 339

A series of 1,089 patients with pregnancy complicated by rheumatic heart disease is presented. This complication occurred in 2.6 per cent of 41,459 pregnancies. The functional-capacity diagnoses according to the New York Heart Association criteria, were 480 (44 per cent) class 1, 1,443 (41 per cent) class 2, 113 (10 per cent) class 3, and 54 (5 per cent) class 4.

The total mortality was 11 (1 per cent) and the cardiac mortality 8 (0.7 per cent). All cardiac mortality was due to decompensation—5 patients died undelivered and 3 died after abdominal delivery.

The class 3 and class 4 cases are completely analyzed. Twenty-six of the patients were delivered abdominally with 3 deaths (12 per cent) and 136 were delivered vaginally with no deaths.

The abdominal group consisted of 5 hysterectomies with 1 death, and 21 cesarean sections with 2 deaths.

The vaginal group consisted of 35 abortions and 107 viable deliveries. Cardiac failure occurred after the fourth month and death occurred in 15 per cent of these cases.

An outline for the management of pregnancy complicated by serious rheumatic heart disease, (class 3 and 4 cases) is presented. The successful management of pregnancy complicated by serious rheumatic heart disease requires a program of medical and surgical obstetrics of the highest order.

In the absence of other obstetric complications the vast majority of patients can be successfully delivered by the vaginal route. When indicated vaginal therapeutic abortion is a relatively safe procedure for the interruption of early pregnancy.

The hazards of labor can be definitely reduced with good antepartum care, careful functional evaluation, adequate digitalization, and shortening of the second stage. The pulse and respiratory rates intrapartum provide a valuable guide to the cardiac status. Abdominal delivery has been performed with decreasing frequency yet it may still have its place for those cases which fail to improve in spite of treatment.

Each patient should be evaluated as an individual problem. Once severe cardiac failure has occurred antepartum, there is a great risk in discharging the patient from the hospital before delivery.

The incidence of spontaneous abortion and premature labor, the duration of labor and the blood loss at parturition in women with serious rheumatic heart disease are not significantly different from these values in normal women.

EDWARD L. CORNWELL, M.D.

Briscoe, C. C.: Cesarean-Section Morbidity and Septic Mortality in Relation to the Type of Operation. *Am. J. Obst.*, 1944 48 16

Septic infection notably peritonitis holds an enviable position as chief of the causes of death fol-

lowing abdominal delivery, accounting for 36.3 per cent of the deaths in Philadelphia in 1941.

The author reviewed all cesarean sections performed at the Philadelphia Lying in Hospital during the past three years. During this period there were 409 cesarean sections performed by 59 operators with 3 deaths, or 0.7 per cent.

Cesarean section performed before labor begins offers the patient the most protection against sepsis.

Postcesarean morbidity rates at the Philadelphia Lying in Hospital during the past three years show superiority of the low section over the classical for the elective case and especially during labor.

Over a third of the women who die in Philadelphia following cesarean section die of sepsis. One half of the deaths occurred in patients who had been in labor over twelve hours before operation. 37 per cent of whom showed signs of sepsis preoperatively. The absolute death rate and the relative death rate from sepsis show superiority of the low operation for the elective case and especially for the patient in labor.

The supposed protection of the Porro operation for the infected patient has been lacking in Philadelphia during the past twelve years.

Reported series of extraperitoneal operations show the death rate from all causes to be from two to five times less than the death rate from sepsis alone for the Porro operations performed in this city.

The operation of choice for the infected patient would seem to be an extraperitoneal cesarean section.

EDWARD L. CORNELL, M.D.

PURPERIUM AND ITS COMPLICATIONS

Rotstein M. L.: Getting Patients Out of Bed Early in the Puerperium. *J. Am. M. Ass.* 1944 13 838.

A series of 150 uncomplicated obstetrical cases were selected at random for the purpose of studying the effects of getting patients out of bed early in the puerperium.

From the historical viewpoint, prolonged bed rest was preferable because of the fear of uterine prolapse. Observations during the period from 1940 to 1941, in London, showed no ill effects as a result of mobilizing puerperal women early.

Of the group observed, 65 were primiparas and 85 were multiparas. Delivery was spontaneous in 51; low forceps were used in 85 deliveries and mid forceps in 8; the remaining 6 were breech deliveries. Episiotomy was done in 117 patients.

Routine management of the patients selected for study was as follows:

1. Immediately after delivery the patient was encouraged to move about in bed.

2. Ergonovine hydrochloride (1/320 gr. or 0.3 mgm.) was given to each patient every four hours for six doses.

3. The patient was catheterized every ten hours if unable to void but no antiseptic solutions were instilled.

4. Routine perineal care was instituted. This consisted of flushing the perineum with sterile water after micturition and defecation.

5. The patient was put on a full diet immediately.

6. Liquid petrolatum was given on the night of the third day.

7. Starting on the third day each patient was made to lie on her abdomen for one hour.

8. A soap-suds enema was given on the fourth morning.

9. On the morning of the third or fourth day if the four-hourly oral temperature had not been above 99.6°F for the preceding twenty-four hours, the patient was allowed up in the chair for two hours, and again for two hours in the afternoon. Forty-five patients or 30 per cent were first allowed up on the third postpartum day and 105 or 70 per cent, on the fourth postpartum day.

10. On the fifth postpartum morning each patient was allowed to walk about as she desired, and she continued to do so until the day of her discharge.

11. Starting on the fifth postpartum day each patient was put in the knee-chest position for twenty minutes. This procedure was carried out each day until discharge of the patient, and its continuance for two weeks, at home, was prescribed.

There were no serious complications in the entire series. The patients felt better and stronger than patients who had not left their beds early and they were able to care for themselves equally as well as the patients who had been confined to bed. An increase in the amount of lochia occurred on arising, but involution occurred more rapidly and morbidity was not increased. Three patients had postpartum bleeding after they had been discharged from the hospital. Uterine retroversion was encountered less frequently than was expected under the usual postpartum management. Prolapse did not occur. Episiotomy wounds healed without difficulty and the patients were more comfortable out of bed. No venous complications occurred. JAMES F. DOXON, M.D.

González, J. B.: Severe Puerperal Fever: the Puerperal Fever of 1921, and Puerperal Fever at the Present Time (La fiebre puerperal grave, la fiebre puerperal de 1921 y la fiebre puerperal de ahora). *See med., B. Air.* 1944, 41, 2.

The author discusses a term introduced comparatively recently into gynecological terminology namely that of "severe puerperal fever" and calls upon those who use it to explain in what way this severe puerperal fever differs from ordinary puerperal fever. He declares there is no difference in bacteriology, pathological anatomy or any clinical difference. The severe cases are ones that have been allowed to become severe by the use of mistaken treatment.

In 1921 he published his first statistics from the obstetric department of the Hospital Teodoro Alvarez in Buenos Aires. There was no mortality in his cases of puerperal fever. Objections were made to his findings and he invited his colleagues to come in and observe his cases and the results. Only one accepted

the invitation and he was obliged to confirm the author's findings.

Puerperal fever is an infection of the genital canal which occurs following delivery the infection being caused by one or several of the ordinary pyogenic cocci. All cases can proceed to normal recovery if the author's strictly abstentionist treatment is carried out. The patient is kept in the best possible general condition no examinations are made of the genital canal and the position is such as to allow free discharge of all lochia from the vagina. There may be a daily gentle cleansing of the vulva with a sponge wet with hydrogen peroxide and blood transfusions suffice to stimulate the defensive forces of the body.

Four cases are described which support his theory. They might be called severe cases as the course was prolonged and one patient had a septicemia and another a thrombophlebitis. The patient with septicemia died, the only fatality in the author's clinic. However the patient had been brought in five days after delivery with a retained placenta.

Cameron C. S. and Graham S.: Antenatal Diet and Its Influence on Stillbirths and Prematurity. *Glasgow M J.*, 1944 143 1

A record was made of the food intake of 300 mothers—100 mothers of still born infants, 100 mothers of prematurely born infants and 100 mothers of normal full time infants. There was no selection of cases in any way and obstetrical causes were not considered. The standard of prematurity was the usually accepted one, namely an infant with a birth weight of 2.5 kg or under. The investigation was made after the confinement and before the mother left the hospital but covered the last three months of pregnancy.

The diet of each of the 300 mothers was then recorded in terms of intake of calories, carbohydrate, fat, protein, calcium, phosphorus and iron. The average amounts of each of these constituents together with the optimum requirements for expectant mothers, are given in Table I. The vitamins were not considered in this study although their importance must not be overlooked.

TABLE I.

	Optimum requirements	Stillbirths	Premature births	Full-term births
Calories	2,500	1644	1710	1946
Carbohydrate (gm.)	350	207	217	217
Fat (gm.)	80	61.9	64.9	80.4
Total protein (gm.)	90	53.4	54.5	73.1
First-class protein (gm.)	50	27.4	29.9	45.9
Calcium (gm.)	1.5	0.76	0.8	1.22
Phosphorus (gm.)	2.0	0.91	0.95	1.37
Iron (mgm.)	15.0	9.0	9.0	11.0
Age		32.1	28.4	28.6
Parity		4.2	2.9	3.13

Scrutiny of the group values indicates the superiority of the diets of the mothers with full time infants in every respect but relatively this is most noteworthy as regards first class protein, calcium and phosphorus, for which the figures for the two other groups are less than two-thirds of those for the mothers with full time infants and of the optimum values. The diets of mothers of still born and prematurely born infants show remarkably little difference from one another. There is a consistent but very slight difference in favor of premature births in respect only of proximate principles, but none in mineral values. Statistical analysis of the figures indicates that the superiority of the diets of the mothers of full-time babies is definitely significant but that the minor differences between the diets of the other two groups are quite unsubstantial, statistically or otherwise.

To test the validity of these findings in a practical way it was decided to supervise the diets of a certain number of expectant mothers and compare the results of their pregnancies with those of a control series. Accordingly, the diets of 500 women attending the antenatal clinic at the hospital were supervised during the last three months of pregnancy.

To serve as a control the records of 500 women attending the antenatal clinic during the same period but whose diets were not supervised were used. The findings are recorded in Table II and as far as they concern stillbirths and premature births are regarded as significant.

TABLE II

	Supervised group	Control group
Stillbirths	21	36
Premature births	51	50
Neonatal deaths (in hospital)	8	10
Infants breast fed on dismissal from hospital	357	276
Average parity of mothers	2.96	3.08
Average age of mothers	28.38	28.8

The results in the present investigation show the relative superiority of the diets of the mothers who bore full term infants. Confirmation of these results was obtained in practice. When the diets of the expectant mothers were improved by instruction and encouragement given at an antenatal clinic by a trained dietician the incidence of stillbirths and premature births was reduced. The results of the second part of the investigation may be taken as indicating the minimum amount of improvement which might be expected if the diets of the expectant mothers were increased to the optimum.

CHARLES BARON, M.D.

Hoenig, E. and Warner, M. P.: Full Term Pregnancy After Removal of the Remaining Ovary at Five Months of Gestation. *Am J Obst* 1944 48 431

The authors report a case of a full-term pregnancy in a patient possessing only one ovary after removal of the remaining ovary at five months of gestation. The

patient was a twenty-seven-year-old para-0 who had had one ovary removed three years before the present pregnancy. During the course of this pregnancy she was admitted to the hospital at the fifth month complaining of severe abdominal pain. A diagnosis of twisted ovarian cyst was made and at operation the remaining ovary was removed.

In spite of the removal of the only ovary and the corpus luteum of pregnancy, this patient continued in her pregnancy uneventfully and delivered a normal infant without incident.

This is another case to prove that the ovaries are not absolutely necessary for the successful continuation of pregnancy after the fourth or fifth month of gestation.

HARRY FIXLER, M.D.

Eastman, N. J.: The Abuse of Rest in Obstetrics
J Am Med Ass 1944, 135: 1077

The abuse of rest in obstetrics is discussed in relationship to the employment of pregnant women in industry and to the deep-rooted teaching of child spacing.

On the basis of the large number of women employed in industry at the present time it is estimated that a minimum of a quarter of a million of these become pregnant every year. Government agencies and the Committee on Health of Women in Industry of the Section on Obstetrics and Gynecology of the American Medical Association are agreed that pregnant women can be employed in industry with safety. Adequate antepartum care and rest periods are essential. Jobs requiring night work, heavy lifting, prolonged standing or having a good sense of bodily

balance should be prohibited. A minimum of six weeks leave before delivery should be granted. Experience in Britain during the present crisis confirms the feasibility of employing pregnant women.

Many employers now discharge women when pregnancy is discovered. Because of this, attempts are made to conceal the pregnancy early prenatal care is avoided and many women seek the aid of the criminal abortionist. As a consequence an unhealthy attitude toward maternity is acquired and the use of contraceptives is compulsory.

The second abuse of rest is associated with child spacing. It has been axiomatic for many years that an interval of two years should elapse between pregnancies. A previous report by this author showed this to be untrue. His conclusions were:

1. There is no appreciable increase in the rate of stillbirths or neonatal deaths when the interval is less than two years.

2. Hypertensive toxemia is least frequent when the interval between the first and second pregnancy is less than two years, increased when between two and four years, and greatly increased when over four years.

3. In the event of previous hypertensive toxemia, the likelihood of repetition is increased the longer the interval.

4. The incidence of premature labor, anemia, postpartum hemorrhage, and puerperal infection was not increased by intervals of less than two years.

5. There was no difference in the ability to nurse.

6. The weights of the mature babies was approximately the same.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

De la Peña, A. and De la Peña, E. Case Report Illustrating Brief Period of Time Necessary to Formation of Large Staghorn Renal Calculus. *J Urol* Balt, 1944 52 108

A case is reported of a thirty-seven year-old female who had a nephrostomy of the kidney on the left side a year before the authors saw her. A urinary tract roentgenogram at the time the authors saw the patient revealed 2 small stones in the left renal area, and the patient complained of colicky pain in the left renal area as well as in the right iliac fossa. A month after this film was taken the patient was seized with right lumbar colic and fever. A film at this time (thirty-eight days after the first) demonstrated the perfect mold of a large stag horn calculus filling the right renal pelvis. Operation was refused. Following this the patient suffered right lumbar pain and fever and passed small calculi. The left kidney was found to be nonfunctional nine months later and the right partially so. At this time operation disclosed the left kidney to be merely a functionless pyonephrotic sac.

Two months later the patient suffered right lumbar pain and a plain roentgenogram demonstrated no appreciable change in the size of the right stag horn calculus as visualized nine months earlier. This stone was removed by nephrolithotomy. The kidney was found sclerotic in the upper pole and the secreting tissue was confined to the lower pole. This was less than a third of the kidney mass. The patient's postoperative course was uneventful.

The case is recorded since here a large renal stag horn calculus of no more than thirty-eight days incubation was observed and the size of the stone was unaltered at operation nine months later.

BLADDER, URETHRA, AND PENIS

Mueller, S. R. and Hamilton, J. B.: The Effect of Testosterone Propionate on the Tonus of the Urinary Bladder. *J Urol* Balt, 1944, 52 139

Cytometric studies designed to determine whether or not the tonus of the bladder may be influenced by androgenic treatment were carried out in 6 men and 2 women. The intravesical pressures observed with the introduction of increasing amounts of fluid into the bladder were higher in all of the men and in 1 of the women following treatment with male hormones. There was an increase in the maximal intravesical pressure developed both before pain or discomfort was first noted and before the pain was sufficiently severe that the test was terminated. The volumes of fluid contained in the bladder at the first appearance of pain and at the onset of severe pain were similar to or slightly smaller than those

that produced similar phenomena prior to medication. In most instances the intravesical pressure at which the first desire to void was experienced was increased upon androgenic treatment, but the volume of intravesical fluid at this point did not vary in a uniform manner.

This augmented tonus of the musculature of the bladder that accompanied androgenic treatment was much in excess of the normal range of variability and could not be accounted for by technical procedures. Neither the increased tonus nor an apparent improvement in control of micturition are attributable to change in prostatic size or consistency.

JOSEPH A. LOFF, M.D.

Pole, F. Recurrent, Nontraumatic Rupture of the Urinary Bladder—a Case Report. *Virginia M Month*, 1944 71 477

The gravity of urinary vesical rupture is emphasized by referring to Campbell's report which showed that from 60 to 80 per cent of the patients with this condition died. It was Campbell's conclusion that delay in treatment and infection of the urine were the most prominent factors influencing the mortality. Hence early operation and the institution of free drainage are paramount in bladder rupture.

The author reports a case of a recurrent non-traumatic rupture of the bladder in a thirty-two-year-old colored male who had a previous history of urethral obstruction with trocar drainage of the bladder seven years previously. During the intervening time the patient was treated for penurethral abscesses and in 1942 an intraperitoneal pelvic abscess due to vesical rupture was drained but cystostomy at that time was deemed impossible because of peritoneal adhesion of the intestine to the anterior surface of the bladder.

On admission in 1943 in view of the patient's past history, and in addition his complaint of severe low abdominal pain of three days duration oliguria, chills fever and generalized abdominal rigidity a diagnosis of vesical rupture was made. The total white blood cells were 20,100 with 92 per cent of polymorphonuclear leucocytes.

At operation the diagnosis was confirmed. Generalized peritonitis was present with free pus in the abdominal cavity. The bladder was found thick and inelastic with a 0.5 cm. opening of the peritoneum communicating with the bladder lumen. The opening was closed with catgut, the purulent fluid was aspirated, sulfanilamide and sulfathiazole powder was implanted in the abdominal cavity and a penrose drain was inserted to the point of vesical rupture. The bladder was drained suprapubically through a separate stab wound. At a later date the urethral strictures were excised, and the patient was discharged from the hospital with a urethral caliber of 22 F.

ROBERT LICH, JR., M.D.

Hatch, W. E., and Wells, A. H.: Actinomycosis of the Urinary Bladder Complicating a Case of Madura Foot. *J. Urol. Balt.*, 1944, 33: 149.

A case of actinomycosis of the urinary bladder which was apparently secondary to a long-standing actinomycosis of the foot and lower leg has been reported, with autopsy findings.

The only important autopsy findings were in the kidneys, urinary bladder and right lower leg and foot. The perineal fat was unusually adherent, but the capsule could be stripped from the kidneys without difficulty. Outer surfaces of the kidneys were finely granular. The kidneys weighed 145 and 160 gm. The parenchymal tissue was unusually pale and somewhat flabby. There was a very slight bilateral hydronephrosis and hydroureter. Microscopic sections of the kidneys revealed approximately grade II patchy interstitial fibrosis and lymphocytic infiltration without thickening of the artery walls. There was no frank granulation tissue or abscess formation in the kidneys. There was no infection or thickening of the walls of the pelvis or ureters. The bladder wall was from 8 to 10 mm. in thickness and was fibrous in nature. The bladder contained about 400 cc. of dark-red, tenacious blood clots. A few tiny blood clots were attached to the bladder wall. The mucosal surfaces were relatively smooth throughout. There were areas of superficial erosion with small patchy areas of superficial charring due to the recent surgery but most of the mucosa appeared normal. Posteriorly the wall was unusually thin, red and edematous. For several centimeters in all directions cellulitis was present in the subperitoneal fatty tissues overlying the urinary bladder. Multiple cuts were made and revealed, besides the diffuse edema of the bladder wall and areas of fibrouslike induration scattered throughout the posterior part of the bladder and involving about one third of the entire organ. No papillary processes or deep ulcerations were found. Microscopic sections of this portion of the urinary bladder revealed frequent small abscesses in a dense fibrous stroma. Large colonies of typical ray fungus were found with the pus cells in these abscesses.

The foot was approximately three times its usual size and the swelling extended up to involve to a much lesser extent the lower third of the leg. There were many tiny sinuses scattered over the skin surface. Sectioning revealed a remarkably dense fibrouslike tissue extending down to the bone. There was some destruction with softening and purulent matter in the lower end of the tibia which was continuous with the processes in the surrounding soft tissues. Smears from the purulent matter in the bone and sinus tracts revealed actinomycetes.

JOHN A. LOER, M.D.

Lich, R., Jr.: The Treatment of Inflammatory Urethral Strictures. *Am. J. Surg.* 1944 65: 38

A rapid, safe and long tried nonsurgical method of dilating urethral strictures of small caliber is outlined. The advantage of oil in the urethra as a filiform

lubricant, and the danger of oil embolism are mentioned. The necessity of frequent bladder and urethral lavage is pointed out, and the use of a 5 per cent lactic-acid solution is advised. In the noninfected case urotropin is advocated as a prophylactic, and the necessity of urinary acidity for its effectiveness is noted. Slow vertical decompression is accomplished by inserting a 20-gauge needle into the tube leading to the urine-collecting bottle. In lieu of the more complex apparatus designed specifically for gradual vertical decompression. The author mentions the possibility of urethral malignancy in instances of repeated urethral bleeding following dilatation.

The method of dilatation of urethral strictures is as follows:

1. A urethral filiform is passed through the urethral stricture.

2. A Phillips follower catheter is attached to the filiform and inserted into the bladder for drainage and dilatation. If the stricture will not permit a Phillips catheter to pass, the filiform is fixed in position for twenty-four hours, after which time a small Phillips catheter will usually traverse the stricture.

3. The bladder is decompressed slowly in the event of chronic massive retention.

4. The dilating catheter followers are increased 2 F sizes every twelve hours until a 22 F caliber is reached.

5. After a 22-F catheter follower is retained for twelve hours the follower and filiform is replaced with a 20-F soft-rubber bevel-edge catheter.

6. The rubber catheter size is increased at twelve hourly intervals until a 26-F size is reached.

7. The rubber urethral catheter is increased 2 F sizes every twelve hours until a 26-F catheter has been in position for twelve hours.

8. Further dilatation and maintenance of the accomplished urethral caliber is then continued with metal sounds used at ever-increasing intervals based on clinical progress.

MISCELLANEOUS

Schnittker M. A., and Lenhoff C. D.: Sulfonamide-Resistant Gonorrhea Treated with Urea and Sulfonamide by Mouth. *J. Lab. Clin. Med.* 1944 31: 639.

Until recently the problem of sulfonamide-resistant gonorrhea has been an important one constituting from 10 to 20 per cent of all cases. Penicillin has now made gonorrhea, in any of its forms, curable in practically all cases.

In an attempt to find a more successful method of treatment for these cases than anterior urethral instillations of silver salts and a safer method than fever therapy, the authors were encouraged by reports of the efficacy of urea in combination with the sulfonamides as a local dressing for wounds to try urea by mouth in cases of sulfonamide-resistant gonorrheal urethritis.

Forty males whose gonorrhea failed to respond to one or more courses of sulfonamide employing 1 gm.

of sulfathiazole or sulfadiazine a day for five days were found to have smears and cultures positive for gonococci. Besides a careful history and physical examination the studies included a complete blood examination a second or third-glass urine specimen for albumin and red cells the fasting blood urea nitrogen and a twenty-four hour urine urea. When all these findings were normal the patient was started on 2 tablespoons three times a day of a mixture containing 325-gm. urea 450 cc. of distilled water and q.s. simple syrup ad. 1,000 cc. This medication was well tolerated and supplied 30 gm. of urea daily. This treatment was given alone for three days. On the morning of the fourth day another fasting blood urea nitrogen and twenty-four hour urine nitrogen were determined, a urethral smear was made and the patient was begun on a sulfonamide the same drug and in the same dosage which had failed previously. The urea and sulfonamide were given together on the fourth fifth and sixth days. The urea was then discontinued and the sulfonamide was given alone for another three days. If at the end of treatment any discharge remained smears and in some instances cultures were made. The patient's progress was followed for another three weeks by two glass tests of the urine and smears.

Of the 40 cases treated 21 (52.5 per cent) showed a rather dramatic recovery the urethral discharge ceased abruptly and completely. The two-glass test and smears remained negative and no urethral discharge reappeared during the three weeks observation period. Study of the 19 unsuccessful cases revealed no relationship of onset of discharge to time of institution of the original sulfonamide treatment. The number of previous attacks of gonorrhea was not related to the end results of urea-sulfonamide therapy nor was the number of previous courses of sulfonamide related to success or failure of urea-sulfonamide therapy.

Fifteen patients of the same type studied with urea-sulfonamides were given double the routine dose of sulfonamide treatment alone with only 3 (20 per cent) successes. In the way of further control studies, 5 patients were given the 30 gm. of urea alone for seven days with no beneficial result. Since many patients had received 1 to 2 gm. of sodium bicarbonate with each dose of sulfonamide it was necessary to perform controls on the sodium bicarbonate. Four patients had sodium bicarbonate alone and 4 patients received sodium bicarbonate in conjunction with the routine dose of sulfonamide. In neither group were there any cures.

Of the 19 failures of urea-sulfonamide therapy 8 responded to anterior urethral instillations of silver salts 2 responded to fever therapy and 9 responded to penicillin administration. Only 5 (12.5 per cent) of the 40 patients experienced any toxic effects from the sulfonamides. In 4 instances these were mild including headache drowsiness conjunctivitis and microscopic hematuria. One patient had a severe reaction with fever malaise and headache after two days of drug treatment.

Laboratory studies revealed slight increases in the blood urea nitrogen and in the twenty-four hour urine urea but drug levels of the blood remained the same. The resistant strains of gonococci were able to grow on concentrations of 0.1 mgm. per cent of sulfathiazole and 2.0 per cent urea chocolate agar plates. These strains of gonococci did not grow in the combined presence of 2.0 per cent urea and 0.35 mgm. per cent sulfathiazole.

The authors conclude that the urea sulfonamide treatment of sulfonamide-resistant gonorrhea may serve a useful purpose when penicillin is not available.

DONALD F. McDONALD M.D.

Sternberg T. H. and Turner T. B.: The Treatment of Sulfonamide-Resistant Gonorrhea with Penicillin Sodium. *J. Am. M. Ass.*, 1944, 126: 157.

Studies have been carried out in 15 selected army hospitals with a view toward determining as rapidly as possible the time-dosage factors in the treatment of sulfonamide-resistant gonorrhea with penicillin. A total of 1,686 patients refractory to at least two courses of a sulfonamide and in some cases to artificially induced fever were treated with total dosages varying from 40,000 to 160,000 Oxford units per case, the individual dose being from 10,000 to 20,000 units given intramuscularly every three hours.

These studies showed penicillin to be a remarkably effective drug in the treatment of gonorrhea. Its use usually caused a disappearance of the symptoms and a reversal of the bacteriological findings within forty-eight hours. One course of treatment with a dosage of 160,000 units per case effected cures in 98 per cent of the cases; a dosage from 80,000 to 120,000 units per case effected cures in 96 per cent and one of 50,000 units in 86 per cent. No significant differences in the final results were noted when a given total dose was administered in individual injections of either 10,000 or 20,000 units. Further more little advantage was gained by prolonging the time of treatment schedules beyond twelve hours.

Factors such as the duration of infection previous fever therapy and race appeared to have no effect on the results of therapy.

Of a total of 126 patients who failed to respond to one course of penicillin 85 were treated with an additional dosage of 100,000 units of penicillin. Of these 78 (91.8 per cent) were cured. Thus, by a second treatment of the failures cure was obtained in 99 per cent of all the cases. No case in the entire series proved to be penicillin resistant.

Complications of gonorrhea responded well to penicillin although the more serious forms of complications required prolonged treatment with higher dosage.

Reactions to penicillin were inconsequential and in no instance was it necessary to discontinue treatment for this reason.

Because of the known effects of penicillin on *treponema pallidum*, the possibility of masking or delaying the development of early syphilis must be considered.

Finally it should be recognized that the treatment of gonorrhea has been completely revolutionized in the past few years first by the introduction of the sulfonamides and, more recently by the development of penicillin. It is clear that the management of gonorrhea now belongs within the sphere of the chemotherapist and that local treatment is rarely necessary and may do more harm than good.

JOHN A. LOYD, M.D.

Page S. G., and Helms L. L.: One-Day Treatment of Sulfonamide-Resistant Acute Gonorrhea with Penicillin: A Preliminary Report. *Virginia M. Month.* 944, 71-73.

Thirty adult males all but 1 of whom had previously received one or more courses of sulfathiazole, were given intramuscular injections of a solution containing 20,000 Oxford units of crystalline penicillin in alternate buttocks every three hours until five doses (100,000 units) were given.

Fifteen of the 30 patients were bacterially negative at the end of three hours, 7 were negative at the end of 6 hours and 1 was negative at the end of nine hours. All were negative at the end of twelve hours. All of these patients were cured insofar as could be determined by an observation period of three weeks with three consecutive negative gonococcal cultures which were taken not less than one week apart and with consistently negative physical and other laboratory findings.

No toxic effects were noted; the blood counts and urinalyses done at three, twelve, twenty-four and forty-eight hour intervals were normal.

JOHN W. BRENNAN, M.D.

Riba, L. W., Schmidlapp, C. J., and Borwoeth, N. L.: The Use of Penicillin for Gonorrhea Resistant to Sulfonamide Compounds: Report of 458 Cases. *Harvard Chic.*, 944 6-73.

A series of 450 sulfonamide resistant cases of gonorrhea were treated with penicillin. One group consisted of 105 patients treated with 160,000 units, 10,000 units being given intramuscularly every three hours for forty-eight hours with 2 (2 per cent) failures. One of the 2 was cured with 1,000,000 units of penicillin. A second group consisted of 112 patients who were treated with 100,000 units, 10,000 units being given intramuscularly every hour for ten hours with 11 (9.8 per cent) failures. These 11 failures were treated again with 160,000 units with 6 additional cures. A third group consisted of 233 patients who were treated with 50,000 units, 10,000 units being given intramuscularly every three hours with 55 (23.6 per cent) failures. Forty-eight of the 55 were successfully treated with 100,000 units (1 with 160,000 unit).

The average age incidence was twenty-three years. The chief source of the infection was casual pick-ups (5.4 per cent). Ninety per cent of the patients had been previously hospitalized in station hospitals for treatment. These 450 cases of gonorrhea had all received oral sulfonamide therapy averaging about

85 gm. each without material benefit or clinical cure. The chief drugs employed were sulfadiazine and sulfathiazole.

Pretreatment examination revealed a urethra, 5 charge in 96 per cent of the 450 cases. Fifty per cent of the cases had positive smears and cultures, 12.4 per cent had positive smears and negative cultures. In 31.7 per cent of the cases in which the smear was positive no culture was made. Six patients with doubtful smears and 6 with negative smears had positive cultures. For 4 with positive smears, 3 cultures were overgrown with contaminants, and 1 with doubtful smears had a negative culture. Urethral smears were diagnostic in 95 per cent of the cases whereas cultures were of definite diagnostic value in only 3 per cent.

The chief complications of gonococcal arthritis in this series of cases were acute prostatitis (6.1 per cent), meatal stricture (13.6 per cent), urethral stricture (12.5 per cent), epididymitis (7.3 per cent), seminal vesiculitis (3.7 per cent), periurethral abscess (2.6 per cent), syphilis (2.6 per cent) and arthritis (0.6 per cent).

The average duration of infection prior to admission was forty-seven and two-tenths days. The average period required for a hospital work-up before treatment was instituted was six and four tenths days. The post treatment observation averaged twenty-three and eight tenths days. The average loss of time from the onset of infection to the return to duty was eighty-one and three tenths days per patient.

On the first clinical day following treatment 51 per cent of the patients had no urethral discharge; in 13 per cent there was only a moist meatus; but in the remainder there were from mucoid to purulent discharges. By the tenth post treatment day 76 per cent had a dry meatus, 7 per cent had a moist meatus and 13 per cent had a discharge. On the tenth day the urine was clear in 76.6 per cent of the patients. All of the prostate glands were examined during the second week and seminal fluid containing penicillin was cultured. Calibration for urethral strictures was carried out during the third week. Follow-up smears were positive in 9 per cent, doubtful in 30 per cent, and negative in 66.4 per cent of the cases. The highest incidence of positive smears was noted in the 50,000 unit group. Of cultures 3 per cent were positive and 2.2 per cent were overgrown with contaminants; the remainder were negative.

Critical review of the failures with penicillin reveals that in 61 of the 63 cases in sufficient penicillin was administered. After sufficient penicillin was given there were still 14 cases in which penicillin failed. Twelve of these 14 cases were retreated with hyperpyrexia and penicillin (100,000 units) with success in 4 cases.

Six of the 10 remaining cases were treated by intensive penicillin therapy (1,000,000 units) with 3 successes. The final 7 cases were treated with sulfapyridine by mouth, urethral irrigations and irrigations of strong protein silver solution with 4

prompt successes. One patient was found to have a contraction of the vesical neck which after trans-urethral resection was followed by cure of the infection.

The authors conclude by suggesting that a total of 160,000 units of penicillin is the desirable dose for sulfonamide resistant cases of gonorrhea and leads to cure of 98 per cent of the cases

DONALD F. McDONALD, M.D.

Culp, O. S. and Kaplan, I. W.: Condyloma Acuminata: 200 Cases Treated with Podophyllin
Ann. Surg., 1944 120 251

Podophyllin has been found to be unusually successful in producing prompt and complete disappearance of condylomata acuminata regardless of size, number, location or duration of the growths. The drug is best applied as a 25 per cent suspension in mineral oil. Anesthesia and hospitalization are not necessary. There is minimal time lost from any type of physical activity.

Most lesions disappear within four days after a single application of the drug. Growths within the urethra usually require two or more treatments. None of the authors' patients required more than four topical applications.

No ulceration or scarring results and the surrounding normal tissue usually is unaffected by the drug. In isolated cases of extensive application under long prepuces some balanoposthitis may develop but thorough washing twenty four hours after treatment will prevent this and not interfere with the end-result.

The convalescence is usually entirely painless but some patients, especially those with extensive involvement of the vagina, may require sedation during this period.

Recurrences or new growths are to be expected since the etiology of condylomata acuminata remains unknown but these likewise respond quickly and completely to the same treatment.

Podophyllin appears to be capable of destroying most types of granulomatous tissue and additional clinical applicability probably will be forthcoming.

The dramatic results obtained in this series of 200 patients with condylomata acuminata on the penis, female genitalia, perineum, scrotum, urethra and anus and the simplicity of the treatment with podophyllin recommend a more general adoption of this type of therapy.

JOHN A. LOER, M.D.

Buchwald, K. W. and Hudson, L.: The Biochemical Effects of Sex Hormones. Acid and Alkaline Phosphatase Activity, Calcium and Phosphorus. *Endocrinology* 1944 35 73.

A series of 63 mature rats were subjected to testosterone propionate and diethylstilbestrol in oil injected subcutaneously for a twenty-eight-day period. These studies were undertaken to study the biochemical process involved in the hormonal therapy of carcinoma of the prostate. The phosphorus intake and output was carefully followed. There was no change in the serum calcium or in the output of calcium and phosphorus in the feces.

The authors found that diethylstilbestrol in male rats caused a reduction of serum phosphorus and acid phosphatase activity of the serum. The alkaline serum-phosphatase activity was unchanged in contrast to the reduced alkaline phosphatase activity of the femurs. This latter finding may be a significant factor in the lack of healing in bony metastasis in patients with prostatic carcinoma.

The female rats subjected to subcutaneous injections of testosterone propionate demonstrated an increased serum alkaline-phosphatase activity which suggests that this hormone is actively stimulating to growth. In this group of animals the acid phosphatase activity of the serum and the alkaline phosphatase activity of the femurs was not influenced whereas, the alkaline phosphatase activity of the serum was increased.

The experimental data obtained is complete and tabulated for clarity. The authors readily admit that this material is in part difficult to understand but add that further work is in progress with castrated animals so that the experiments approach more nearly the picture with which we deal in the human being.

ROBERT LACY, JR., M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Lyford J., III Scott R. B., and Johnson R. W.
Jr.: Polyarticular Arthritis and Osteomyelitis Due to Granuloma Inguinale *Am J Syph.* 1944 28 583.

The authors point out that polyarticular arthritis and osteomyelitis due to granuloma inguinale are being seen with increasing frequency and having previously given the detailed findings of 1 case review 2 additional cases in this report. Bone and joint involvement is only rarely mentioned among the reported cases of granuloma inguinale but it occurred in all 3 cases reported by the authors.

A number of interesting and important facts regarding this disease are brought out in this report. In none of the patient's families was the disease found and as these patients had draining ulcers which would cause the bed covers to be soiled frequently this is strong presumptive evidence that mere contact with material from active lesions of granuloma inguinale is insufficient to spread the disease. It has been pointed out that individual susceptibility to this disease varies greatly.

It has been previously suggested by workers in this field that this disease may be a systemic one and the authors are inclined to conclude from their 3 cases that this is probably true. All of their patients had marked anemia more or less chronic, and relative resistance to therapy. The course of the disease was marked by irregular spiking temperatures over a long period of time with loss of weight of from 15 to 40 lb during the active stage of the disease and episodes of spontaneous remissions and exacerbations. The authors point out that osteomyelitis and arthritis are frequent manifestations of systemic processes and that the onset of these joint pains are at first migratory followed in a few days by a fusiform swelling of the joints of the toes and shortly thereafter by swelling and pain in the elbows, wrists, and knees. The joints become markedly swollen and ultimately develop draining granulating ulcers which rupture from within outward. None of the joints examined contained much free fluid during the acute state and the exploration of 1 elbow joint revealed the synovium to be thick and friable while the articular cartilages remained clean and smooth. Microscopic examination of a case with progressive osteomyelitis of the bones of the hand and forearm revealed granulation tissue containing plasma, cells, and macrophages filled with Donovan bodies. The authors emphasize what has previously been mentioned that the disease granuloma inguinale should be diagnosed only when Donovan bodies can be demonstrated in smears or biopsied material from the lesions. In all of their 3 cases the Donovan bodies were readily demonstrated in the specimens

prepared by the routine method of fixation and stained by the usual technique with hematoxylin and eosin.

The mode of spread of this infection was not determined in the authors' cases, but the authors are inclined to think that their cases suggest that the metastases were hematogenous rather than lymphogenous as has previously been suggested. In all of their cases there was a systemic dissemination of the disease with a massive polyarticular arthritis and, ultimately, ulceration of many of the joints and widespread destruction of the bone. The spine, the hip joints, the forearm elbow knees etc. etc. showed joint involvement, and the authors believe that granuloma inguinale can be considered a systemic as well as a local disease. No specific treatment is advocated and 2 of their patients are still under treatment while the third several years after leaving the hospital appeared to be well in good condition and with no lesions.

PART C. COLVER, M.D.

Clay R. C.: Dupuytren's Contracture: Fibroma of the Palmar Fascia. *J Surg* 1944, 120: 274

The author sets out to show that Dupuytren's contracture is due to a neoplasm, a cellular fibroma of the palmar fascia. He reviews the theory of its etiological causes. He quotes the work of Abbott, and points out that Dupuytren himself thought the disease resulted from repeated trauma. Knewel, Koch, and Mason have suggested trauma, local inflammation, lead poisoning, loss of fat with aging and embryonic malformation. Best points out that the histories of all cases are somewhat unconvincing. These authors conclude that the etiological factors in the contracture are unknown. Brooks recorded a case associated with an aneurysm of the axillary artery and Clay stated that the theory that the contracture is due to a neoplasm is not frequently proposed. Many authors are quoted, among them Ewing of whom Clay thinks that he implies a recognition of its neoplastic character.

In general all authors agree that the first symptom of contracture is a palpable nodule in the palm. The material for this study came from 22 hands of 17 patients operated upon for Dupuytren's contracture in the Johns Hopkins Hospital, Baltimore. The histological pictures of the tissues excised were surprisingly uniform. In 14 of the patients there were areas of rather cellular fibromas interspersed with areas of hyaline-appearing fascia. The fibromas were rather poorly demarcated composed of small spindle-shaped cells with elongated nuclei which contained finely granular chromatin particles. No mitoses were seen and the cells were all quite similar. While the fibromas slowly invaded the surrounding structure, they did not metastasize.

The author believes that no true conclusion is to the etiology of Dupuytren's contracture has pre-

viously been reached that a palpable nodule in the palm was the first symptom of the disease, even preceding the onset of contractures of the fingers and that there is a marked predominance of males, 15 of the 17 patients in this series being males. Among the 14 patients of this series only 1 gave any suggestive history of trauma to the palm.

PAUL C. COLOMBA, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Hurt F., and Flo B. C. Traumatic Synostosis of the Distal Third of the Radius and Ulna. *Surg* 1944, 15 804.

Whereas congenital synostosis of the proximal third of the radius and ulna is fairly common traumatic synostosis appears to be rare, only 2 instances having been reported. This article reports an instance of traumatic synostosis of the radius and ulna in a twenty seven year-old soldier who was struck across the lower forearm by a sledge hammer in 1934. Splints were applied following which he had satisfactory rotation which gradually diminished. In the last five years the arm was fixed in midpronation.

The exostosis was removed at operation through an incision on the extensor surface. A line of cleavage was found in its center which corresponded to the pseudarthrosis in the roentgenograms. Following the operation the soldier had complete painless range of motion.

The authors concluded that both the radius and ulna were traumatized without deformity to either

Fig. 2. Final results showing further absorption of the remaining stump of bridge.

which resulted in a gradually increasing ossifying hematoma, that eventually formed a pseudarthrosis

RUDOLPH S. REICH, M.D.

Mazzini O F: Interilcoabdominal Disarticulation for Hydatidosis of Pelvic Bones (Desarticulacion interilcoabdominal por hidatidosis de la pelvis osea)
Bol Acad argent cir 1944 28 371

A fifty five year-old Italian laborer had been complaining for five years of pain in the coccygeal region which radiated toward the left gluteal area. The pain was of intermittent character was aggravated by the erect position lasted a few hours or days and recurred at irregular intervals.

At the time of admission to the hospital the patient's temperature was 100.9 degrees. A tumefaction was found in the left gluteal region the local temperature was increased, and the overlying skin was red. An incision furnished abundant pus containing the staphylococcus aureus and membranes which were found to be parts of hydatid cysts. A

Fig. 1. Synostosis prior to surgery showing faintly a pseudarthrosis.

fistulous tract remained after the incision. Fifteen months later a fistula was still present, the secretion was seropurulent. A probe introduced 10 cm deep reached the sacrum. The sacrococcygeal region was painful to touch. The gait was slightly impaired. Casson's intradermal reaction for the echinococcus was positive. X rays revealed a sacral lesion.

A diagnosis of hydatid cyst of the sacrum was made. Under spinal anesthesia the posterior aspect of the sacrum was exposed through a Zuckerkandl incision. Fungus masses were curetted and after the sacrum was trephined, a cavity containing hydatid membranes was entered. A portion of the sacrum and coccyx was resected. A drain was placed into the wound. The after treatment consisted of injections of a polyvalent antiparasitic vaccine and the administration of sulfa drugs.

Six months later a fistula was still present. Pain had not recurred after the intervention. The fistula was treated with injections of bismuth paste.

Three years later a minute orifice surrounded by an ulcer was still present within the postoperative scar and a seropurulent secretion was noticed. Under spinal anesthesia the old scar and the fistulous tract were excised, fungus masses were curetted and a drain was inserted.

Subsequent roentgenograms demonstrated a condensation of osseous tissues.

The author concluded from his observations that the disease did not make any progress since the first intervention, but no claim of a cure could be made because minimal lesions or lesions that could not be visualized in roentgenograms may have been present. Although no biological method of therapy is efficient in 100 per cent of the cases, the employment of antihydatid vaccines is recommended after operations.

JOSEPH K. NARAT, M.D.

Christmann, F. E.: Interilioabdominal Disarticulation for Hydatidosis of the Pelvic Bones (Disarticulation Interilioabdominal pro Hydatidosis d. la pelvis ossea). *Bol. Acad. argent. ci.* 1944, 31: 386.

The author states that Leighton reported 3 cases of interilioabdominal disarticulation and collected 103 cases from the literature.

A forty-seven year-old Yugoslav peasant admitted with the diagnosis of osteochondromatosis of the right femur and hip. First experienced pains in the involved regions five years prior to admission. Gradually a hard tumor developed in the region of the anterosuperior iliac spine. The progressive growth finally caused interference with the gait. Radiotherapy had to be abandoned on account of the pains produced by it.

At the time of examination the overlying skin was only slightly altered. It had a pronounced luster and few telangiectases were visible. The local temperature was increased. The tumor had a hard consistency which, however, was not uniform.

Roentgenograms showed a distention of the superior metaphysis of the involved femur with destruc-

tion of the compact parts of the bone and invasion of the adjacent soft parts.

The slow evolution of the tumor and preservation of the general condition of the patient justified the assumption that the tumor originated in cartilaginous tissue. A biopsy furnished tumor tissue of soft consistency and white color. A diagnosis of chondrosarcoma of the femur was made. Roentgenograms of the chest did not show any metastases.

Under spinal perineal anesthesia supplemented by cyclopropane interilioabdominal disarticulation was performed. The external and hypogastric arteries were ligated. In view of the fact that the pelvis was invaded by the tumor disarticulation of the hip joint was replaced by the atypical interilioabdominal disarticulation through the pubic and sacroiliac articulations.

The patient was discharged from the hospital four and one half months after the operation. The histological diagnosis was chondrosarcoma.

In another instance an intelligent man thirty years of age was admitted with complaints of pains in the pelvic region and the inability to walk. He had difficulty in standing on his feet. Several clinics refused to treat the patient who concluded that his condition was incurable. He asked to be relieved by any means including amputation, but refused the biological treatment of hydatidosis of the pelvic bones.

The very large infected, hydatid abscess was drained and numerous sequestra were removed from the osteomyelitic coccyx. The coccyx was nearly completely destroyed and the femoral head was separated from the neck. An interilioabdominal disarticulation was performed and the patient survived the operation two years. The author performed the operation in 1911 because he was convinced that the biological treatment of hydatidosis would not exert any marked effect on the stability of the femur or the osteomyelitis of the coccyx.

The author changed his opinion since the operation was done and would now apply autogenous therapy, he would attempt to correct the dislocation by continuous traction and would treat the osteomyelitis with sulfonamides and excision of the sequestra. Calcagno's reports on the subject of biological treatment of hydatidosis sound very convincing.

In 1913 or 1914 Churo performed a successful interilioabdominal disarticulation on account of an advanced conofemoral tuberculosis. Recently Sir Martin performed a similar operation on a patient who made an uneventful recovery.

JOSEPH K. NARAT, M.D.

FRACTURES AND DISLOCATIONS

Swart, H. A., and Miyakawa, G.: Fractures of the Femur. Results of Treatment of 179 Patients. *Am. J. Surg.* 1944, 65: 221.

The authors present the results of treatment of 141 fractures in 179 patients from June 1, 1935 to May 1,

1942 All were fractures of the femur in 3 patients both femurs were broken and in 2 patients treatment was given twice for femoral fracture. There were 18 fractures of the neck of the femur 36 intertrochanteric fractures 23 subtrochanteric and upper third fractures, 69 in the middle third of the shaft and 28 in the lower third of the shaft.

Details as to age diagnosis and length of time following injury when treatment was instituted are given. Comments are made regarding each of the treatments for the different types of fractures.

The authors believe that the use of the Smith Petersen nail is still the best method of treating fractures of the neck of the femur although there have been many failures even when this apparatus is correctly applied. Certain factors militate against success in treating this fracture no matter what is done.

The Roger Anderson well-leg splint was used successfully in intertrochanteric fractures in patients who could be kept alive. The authors have had no experience with the use of Smith Petersen nails with side-arm extensions but if patients can be made ambulatory following this operation better results should be expected.

In treating subtrochanteric fractures they believe that open operation with the use of two vitalium plates is the method of choice.

Results with Russell traction in the treatment of upper and middle third fractures have been so good that they are enthusiastic about the method. Union results in a comparatively short time and the degree of knee stiffness is less than when other methods are used.

Disability following fractures of the lower third of the femur is still high, but good anatomical position of the fragments with the use of two- and three wire Kirschner traction as described has been obtained.

EMIL C. ROBINSON, M.D.

Jack, E. A.: Evacuation of the Fractured Femur; the Tobruk Plaster and Other Methods Used in the Middle East. *Lancet* Lond. 1944, 247 11.

The transportation of a casualty with a fractured femur over long distances always has been a problem of considerable difficulty. In the North African campaign a method was worked out to immobilize the leg satisfactorily—to negotiate the transportation with a minimum of pain and with the least possible chance of complication.

The surgeons in the hospital around Tobruk found the so-called Tobruk plaster very satisfactory. An extension strapping was applied to the leg, and then a long leg plaster cast was applied from the groin to the toes with gaps in the cast over both lateral regions to allow the straps to be pulled through. A Thomas splint was threaded over the plaster cast and the straps were tied around the foot-end of the Thomas splint under tension. Finally a second layer of plaster cast was used to envelop the splint and the first cast. This method had several drawbacks. It was difficult to apply a long leg plaster when the femur was shattered and the thigh completely un-

stable. The manipulation caused the condition of the already shocked patient to become worse and finally inspection of the wound during the trip was not possible. These disadvantages were partly overcome by the so-called modified Tobruk plaster.

The modified Tobruk plaster technique consisted of (1) reduction and fixation of the fracture by skin traction on a Thomas splint, and (2) stabilization of the limb and splint with plaster. The wound was surgically treated and an extension strapping was applied to the lower leg from a point about 2 inches proximal to the knee joint line. An ankle felt strap was applied. The knee was held in 15 degrees of flexion. A Thomas splint was threaded over the limb and the straps were tied around the foot-end of the Thomas splint. The leg was padded with special attention to the patella and the tibial crest.

The leg and Thomas splint were then covered with from 6 to 8 layers of loosely wound plaster-of-Paris bandages, the plaster being closely molded to the lateral side of the thigh to prevent the Thomas splint from slipping medialward. It has been found that if this was not done the Thomas ring would very frequently press against the anus and bulbous ureter and thereby cause retention. Finally a foot piece was added to prevent equinus deformity of the foot.

It is emphasized that under no circumstances should reduction of the fractured femur be attempted in this manner.

The advantages of the modified Tobruk plaster are (1) the fracture is immobilized under full view of the wound (2) the method is simple, quick and can be done at the earliest possible opportunity, which reduces operative shock and (3) the thin layer of cast can be easily removed and very easily replaced if it should become necessary to inspect a wound.

GEORGE I. REISS, M.D.

Truog, C. P. "Ring Sequester as a Complication of Fixed Skeletal Traction." *Am. J. Roent.* 1944, 52 64.

Steinmann pins were passed through the upper tibial fragment and the lower tibial fragment or calcaneus in 6 male patients of various ages (2 negroes and 4 whites) all suffering from fracture of the tibia and fibula. The pins were incorporated in plaster casts which extended from the toes to above the knees with about 15 degrees of flexion at that joint. The patients then became ambulatory.

All of these patients complained of pain about the upper Steinmann pin and all developed draining sinuses following removal of the pins in from ten to forty-eight days after they had been inserted. Roentgenology disclosed in each case, in addition to more or less delayed union, a typical "ring" sequestrum consisting of abnormally dense shadow around the canal from which the pin had been removed and a fairly marked resorption of bone around the ring of dead bone itself. Sequestrectomy confirmed the diagnosis in 5 instances.

A seventh report is appended in this case Kirschner wires were used the consequent sequester not

being as clearly demonstrated as the sequestra occurring with the use of the Steinmann pins.

The etiology of these sequestra is probably pressure necrosis plus a low grade of infection.

JOHN W. BROWNMAN, M.D.

ORTHOPEDICS IN GENERAL

Rosenberg, E. F., Baggenstoss, A. H. and Hench, P. S.: The Causes of Death in 30 Cases of Rheumatoid Arthritis. *Ann Int. M.* 1944 30 903

Of 30 patients of rheumatoid arthritis at the Mayo Clinic who underwent autopsy examination after death, 10 died from the rheumatoid arthritis itself, 8 died because of the treatment itself and 12 died of causes which were unrelated to the arthritis or the treatment.

Cardiac lesions were found in 24 cases to which death was directly attributable in 7 patients. In 3 instances, death was preceded by congestive heart failure with anasarca. One death was the result of coronary occlusion, myocardial degeneration, and edema in a child aged nine years. Four patients died from active subacute or chronic rheumatic carditis without pulmonary or systemic edema, the heart failure resulting from active rheumatic inflammation in every case.

There were 2 deaths due to the kidney condition the result of acute pyelonephritis and oliguria following typhoid fever therapy.

Chronic bronchiectasis and diffuse pulmonary supuration were responsible for 2 deaths and in 3 instances death was the result of massive pulmonary embolism 2 of the latter deaths occurred after orthopedic manipulations and the application of casts. Three patients died from bronchopneumonia which was acquired during the course of treatment of the arthritis. Two deaths were caused by pulmonary fat embolism which may have been the result of fat released following manipulation or the result of fractures of osteoporotic bone containing large marrow spaces filled with fat. There was 1 instance of death resulting from massive collapse of the lungs in a male aged thirty-four who was overweight and had severe spondylitis and a large incisional hernia.

Two patients died after long periods of chronic diarrhea, the result of exhaustion.

It is suggestive from this study that rheumatoid arthritis is associated with or predisposes patients to certain fatal visceral lesions, the most striking being rheumatic heart disease. There was a high incidence of cardiac lesions similar to those of rheumatic fever although there was a history of rheumatic fever in only 2 of the 30 patients.

It is noteworthy that the deaths related to therapy were unusually high. Ordinarily harmless medical and orthopedic procedures proved fatal.

Although renal lesions are rare in rheumatoid arthritis and common in gouty arthritis microscopic renal lesions were frequently encountered.

RUDOLPH S. REICH, M.D.

Dandy, W. E.: The Treatment of Recurring Attacks of Low Backache Without Sciatica. *J. Am. M. Ass.*, 1944, 135 75

Defective discs are caused by an inherent weakness of the lumbar spine due to a shift of the planes of the lateral articulations between the last three lumbar vertebrae and the sacrum. Normally in the first two lumbar vertebrae the lateral joints parallel the spinous processes. In the third lumbar vertebra the plane of the lateral joints is turned laterally from 15 to 25 degrees. In the fourth from 25 to 45 degrees, and the plane of the lumbosacral joint forms a 60 degree angle with the spinous processes. Trauma causes these joints to loosen and transfers increasing injury to the discs.

The gross pathological changes in the so-called concealed discs are characterized by a small protrusion, fluctuation, adherence to surrounding structures, and by opacity of the overlying ligaments. When incision is made the instrument dips into a cavity and frequently sequestra can be extracted.

The mechanism of pain and sciatica in defective intervertebral discs cannot be stated with certainty. It is believed that swelling of the joint capsule or slipping of the lateral facets is responsible for unilateral backache. However, a combination of all three, lateral joints and disc, is in one way or another responsible for the backache.

The history usually reveals recurrent attacks of low back pain with or without sciatica. The attack usually lasts from two to three weeks and is brought about by a heavy lift, sudden twist, or sudden movement or there may be no apparent precipitating cause.

It is possible to make a diagnosis of defective disc causing backache from signs and symptoms and x-ray findings in from 95 to 98 per cent of the cases. Recurring attacks of low lumbar backache associated with sciatica are pathognomonic subjective evidence, and narrowing of an intervertebral disc observed by means of x rays is objective evidence of defective discs.

The inadvisability of the use of contrast medium for the diagnosis of defective discs is illustrated in the following four points:

1. Only large discs produce a filling defect; these comprise only 25 per cent of the cases.
2. The information gained is unreliable.
3. Their use is painful.
4. There are temporary or permanent after effects.

Spinal tumors, especially tumors of the cauda equina, present the only difficulty in the differential diagnosis. If tumors are suspected a lumbar puncture is indicated. When a disc is defective the vertebral body is more movable than normal. When the spinous process is pushed caudally with an instrument, increased mobility can be elicited, and this is indicative of a defective intervertebral disc.

The operative treatment has for its objective the complete removal of the disc by curettage and the baring of the bone surfaces to allow bony union.

occur. The bone surfaces offer a broad surface for fusion. Stabilization of the lateral joints usually follows. Fusion of the lateral joints has no practical value because of the minor part they play in the stabilization of the spine. It has been shown that there was no movement in the joints three months after removal of the disc.

Spinal fusion is never necessary in the treatment of ruptured intervertebral discs. It has been used by neurosurgeons who had obtained poor results following removal of the disc alone. There are two reasons for the unsatisfactory results:

- 1 Failure to remove the disc completely
- 2 Failure to recognize multiple intervertebral discs

A total of 32 discs were removed from 20 patients. Approximately 25 per cent were of the large variety. The remainder were concealed discs. The author found multiple discs in 80 per cent of the cases.

There are three possible causes for continuing pain after operation:

- 1 Recurrence of the original disc, which is very unlikely
- 2 Another disc that was missed
- 3 A tumor of the spinal cord or cauda equina (1 per cent)

Psychoneurotic backaches are nearly always continuous, are not accentuated by coughing or sneezing and have a tendency to spread to the shoulders and head. Such extensions have no organic basis.

GEORGE I. RUSS, M.D.

Swartout, H. O., and Frank, W. P.: Multiple Familial Cases of Poliomyelitis. *J Am M Ass* 1944, 125: 488.

Of a total of 721 patients with poliomyelitis admitted to the Contagious Disease Unit of Los Angeles County Hospital in 1943 the author found that 67 cases or 9.29 per cent, came from families with multiple cases. This is compared to the figures of the previous five-year period (1938 through 1942) in which of 403 cases of poliomyelitis reported to the Los Angeles County Health Department only 22 cases or 5.4 per cent were in families with multiple cases.

This difference between 9.2 and 5.4 per cent in the incidence of multiple familial cases is attributed to the fact that in 1943 not only were cases diagnosed by the finding of flaccid paralysis and the other acknowledged signs of poliomyelitis but, in addition the presence of muscle spasm was taken into account. The author stresses the presence of muscle spasm in the diagnosis of poliomyelitis. Though mild degrees are often difficult to perceive and may be missed the type of spasm characteristic of poliomyelitis may continue for weeks or months thus being differentiated from the temporary muscle soreness and stiffness which accompanies other diseases.

To confirm the diagnosis spinal fluid examination was done in 66 of the 67 cases. Two cases showed bloody taps but of the remaining 64, 52 or 81.2 per cent had spinal-fluid findings of more than 10 cells per cubic centimeter or a total protein above 65 mgm per cent and thus were considered positive. The author admits that in the cases unconfirmed by spinal-fluid examination and without physical findings other than persistent muscle spasm the diagnosis of poliomyelitis cannot be definitely established. Nevertheless the diagnosis appeared justifiable when the history was suggestive and when muscle spasm persisted for weeks after the temperature became normal.

The 67 cases diagnosed in 1943 were also reviewed in the light of diagnostic criteria used in previous years. Studied in this way it was found that of the 67 cases, 12 would not have been recognized and 5 probably would not have been recognized.

It is the author's opinion that the concept of spasm in poliomyelitis makes it possible to diagnose cases on the basis of very mild physical findings. Also the lack of recognition of these cases in previous years may account somewhat for the difference between the large number of adults who have protective substances in their blood against the poliomyelitis virus and the small number who have had the disease. One-sided spasm unrecognized and untreated may also account for the frequent orthopedic problems of unexplained scoliosis and leg shortening.

DANIEL H. LEVINTHAL, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Northcroft, G. B. and Morgan, A. D.: A Fatal Case of Traumatic Thrombosis of the Internal Carotid Artery. *Brit J Surg* 1944, 35

A signalman aged thirty-one was walking along a military road, when a piece of loose rope dangling from a lorry travelling in the same direction wound itself around the patient's neck, threw him to the ground and then unwound itself without dragging him along. Though he felt faint and was suffering from a superficial laceration in the right parietal region the patient was able to walk to the Unit Medical Officer. At the nearest reception station a single stitch was inserted in the scalp wound. Bruising of the left side of the neck was noted and the patient suffered slight amnesia. On the following morning his neck showed superficial abrasions more marked on the left side with a swelling of the left sternomastoid muscle just above the clavicle which was thought to be a hematoma. Superficial examination of the central nervous system showed no abnormality. An hour later while the scalp wound was being redressed, the patient did not respond readily when spoken to; twenty minutes later he had lapsed over in bed and jerky movements occurred in the right arm and leg. Fifteen minutes later he was completely unconscious could not be roused, and had a complete right flaccid hemiplegia. Two hours later an exploratory temporal burr hole was made. There was no evidence of extradural bleeding, the dura was not tense and on incision, normal cerebrospinal fluid escaped. The left lateral ventricle was tapped and 5 cc. of clear colorless fluid were withdrawn and the wound was closed. Seven hours later his unconsciousness had increased to deep coma, the temperature was normal, pulse 40 and irregular, and respiration so. The right hemiplegia remained unchanged and he had developed cataplexia in the left arm. On the following morning forty-eight hours after the accident and nineteen hours after operation, his general condition became worse and he died.

At postmortem examination two-thirds of the left sternomastoid muscle was found to have been ruptured a thinned-out strip of muscle being left at the level of the injury. The first 1½ inches of the left internal carotid artery were transformed into a hard bluish spindle-shaped swelling as a result of traumatic thrombosis. The main thrombus lay just above the origin of the internal carotid artery extending upward for 1½ inches. The original lesion was presumably a tearing of the intima and media with extravasation of blood into the media which raised both the intima and media from the outer layers of the vessel wall. As the hemorrhage increased in size, the lumen of the vessel became narrowed and finally it was completely obstructed in the

form of an inverted valve with the thrombus blood below it. Following total occlusion, more recent thrombosis occurred above the level of the injury spreading upward into the petrous and cavernous portions of the vessel to continue into the left middle cerebral artery which resulted in massive infarction of the left cerebral hemisphere. The spread of thrombosis was found to involve the left half of the circle of Willis and most of the left middle cerebral artery.

HAROLD C. OGDEN, M.D.

Tubbs, O. S.: The Effect of Ligation on Infection of the Patent Ductus Arteriosus. *Brit J Surg* 1944, 3

Nine patients from fifteen to twenty-six years of age were operated upon for patent ductus arteriosus complicated by subacute endocardial infection. Essentially the technique used was that originated and described in detail by Gross (*Ann. Surg.* 1939, 110:321). Six of these patients are well to-day from fifteen months to over four years after operation. The type of bacterial infection (streptococcus viridans haemophilus influenzae staphylococcus streptococcus viridans and Gram-negative bacilli) which complicated the anatomical anomaly did not seem to exert any effect on the operative result. Although the bacteria in the blood might persist for some time following the ligation, the blood would eventually become sterile, the diastolic pressure rise permanently to normal figures, the murmurs practically disappear or markedly regress, the patient's physical powers rise, and the body weight and development proceed more satisfactorily than before the operation. This dramatic turn in events occurred in 1 patient in whom the sulfonamides had previously failed to curb the septic manifestations.

Of the 3 patients with fatal results one lived for eight weeks and died of complications not strictly ascribable to the operation itself, another succumbed to acute heart failure at the time of operation, and the third died following an incorrect diagnosis, there being two aneurysms of the pulmonary arteries which in a preoperative roentgenogram were overlooked or falsely interpreted as an enlarged gland. This patient lived for four months after operation and apparently died as a result of recently developed concurrent involvement of the mitral and aortic valves. The pulmonary end of the opening into the operatively obliterated ductus arteriosus was free of granulations but unfortunately there was no evidence to determine whether granulations had been present originally.

As a result of the author's experiences with this condition he concludes that symptoms of infection complicating a patent ductus arteriosus must now be considered an absolute and urgent indication for operation, that the supervention of infection should be diagnosed early and that any patient with a

patent ductus who runs an unexplained fever for more than two weeks should be suspected of this complication
JOHN W. BRENNAN, M.D.

BLOOD TRANSFUSION

Shies, E. L., and Lederer, M.: Uncontrollable Hemorrhage after Dicumarol Therapy with Autopsy Findings. *Ann Int M* 1944, 31: 332

A case is presented in which an uncontrollable dicumarol state was produced and in which the bleeding that ensued was a contributory cause of death. The patient, seventy-nine years of age, was admitted with bleeding of the gums of five days' duration and hematuria of three days' duration. She had received 500 mgm. of dicumarol orally each day for twenty-one days because of a diagnosis of thrombosis of a retinal vein, and during this period no prothrombin estimations had been made. Citrated transfusions were partially but ineffectually successful in combating the dicumarol state.

The authors warn that this drug should not be given unless daily blood prothrombin and coagulation times can be accurately determined and the patient is kept under close observation.

WALTER H. NADLER, M.D.

Malzels, M.: Processing of Plasma with Kaolin. *Lancet Lond.* 1944, 247: 205

Blood banks particularly in wartime carry reserves in excess of probable needs and to avoid waste plasma from surplus blood is retained for use in shock. The present article describes the processing of such plasma with kaolin and suggests that the resulting product when employed therapeutically is less likely to produce toxic reactions than material that is not treated with kaolin.

Normal plasma and serum are more or less opaque and the development of opalescence due to the growth of contaminating bacteria will be masked by the cloudiness originally present. Hence in order to eliminate infection as far as possible and to obtain a clear fluid in which the growth of any surviving bacteria may be quickly detected it has been customary to filter the plasma before it is stored. Unfortunately filtration does not completely solve the storage problem for both filtered and unfiltered plasma and serum contain unstable substances. In the case of plasma, these are fibrinogen and a lipoid-globulin complex while in the case of serum the complex alone is the chief cause of instability. The instability of plasma is actually enhanced by passage through filter pads which convert fibrinogen into fibrin. This fibrin then appears as clot in any filtrate obtained and eventually clogs the filter pads and brings filtration to an end. There are several methods of removing fibrinogen from plasma, but most of these fail to deal with the residual lipoid-globulin complex. This complex is finely dispersed in fresh plasma and serum but aggregates and precipitates during storage and thus reproduces the original problem of a murky fluid in which cloud

may be due either to bacterial infection or to sterile organic deposits. McFarlane's ether freeze process (1941) removes both fibrinogen and lipoid-globulin complex and gives a clear sparkling stable fluid but for technical reasons it is unlikely to come into general use until after the war. Other methods of storing liquid plasma are more or less makeshift. Removal of fibrinogen and filtration are common to all and under favorable circumstances the liquid product may remain clear for about a year.

Because of the difficulty of keeping liquid plasma and serum the present tendency is to avoid storage of liquid products and to dry all material after spin-freezing, it being assumed that if the liquid material were apparently sterile before drying then no infection of the dried product would occur in its sterile container. It follows that to ensure sterility before drying the liquid to be processed must first be filtered and this in the case of plasma necessitates a preliminary removal of fibrinogen. In general therefore the processing of plasma involves filtration and this in turn demands defibrination.

The author describes his method of removing fibrinogen from plasma by adsorption on kaolin. This method adds nothing soluble to the treated plasma and may perhaps remove toxic substances. After removing the fibrinogen the product obtained may be filtered and dried.

Transfusion with this material has been particularly free from reactions. J. M. MORA, M.D.

Lyons, R. H., Jacobson, S. D., and Avery, N. L.: Increases in the Plasma Volume Following the Administration of Sodium Salts. *Am J M Sc* 1944, 208: 245

It has been demonstrated that the plasma volume does not remain fixed even with mild dehydration and will decrease in proportion to the severity of the dehydration. In normal subjects dehydration induced by the administration of a low salt diet and ammonium chloride or by the intravenous administration of 2 cc. of mercupurine is associated with a significant fall in the plasma volume. Under these circumstances it appears that the plasma volume is not well supported by the extracellular fluid and that the loss of water and salt, coincident with the diuresis, is associated with the fall in plasma volume.

The authors note that if the plasma volume is reduced by relatively small decreases in the body water it would appear likely that the reverse situation would also be true. The administration of sodium salts sufficient to produce a positive sodium balance along with sufficient water should increase the volume of the extracellular fluid and presumably the plasma volume as well. These studies were undertaken to evaluate the effect of ingestion of large amounts of sodium salts with water *ad lib* on the plasma volume of normal subjects. The methods employed are given in detail.

From results obtained by the authors it is apparent that the addition to the diet of large amounts of sodium bicarbonate or sodium chloride results in sig-

nificant increases in the plasma volume. The consistent increase in weight noted in these subjects was the result of the retention of sodium and water and represents chiefly an increase in the extracellular fluid portion of the total body water. Although there was considerable variation between the change in the plasma volume and the change in the body weight after the first day of sodium-bicarbonate administration a fairly constant relationship was shown between the change in the plasma volume and the change in body weight at the end of forty-eight hours. The authors note that the plasma volume of normal subjects cannot be assumed to be constant as it will vary with reasonably small changes in the water content of the body and presumably with the sodium balance of the individual.

The increase in the plasma volume following the administration of sodium salts with fluids *ad lib* suggests that this might be useful in the restoration of the plasma volume after bleeding in individuals who may be mildly dehydrated. These studies suggest that the administration of large amounts of sodium salts as a preoperative measure will increase the plasma volume as well as predispose to a favorable water balance. This might be of value when a considerable blood loss is anticipated.

The hematocrit, hemoglobin concentration, and red blood-cell count fail to change in proportion to the change in the plasma volume. The cell elements in the antecubital vein from which the samples were drawn had not undergone the degree of dilution found by the direct determination of the plasma volume. Ebert and Stead explained that there are shifts in the concentration of red blood cells between the smaller and the larger vessels with alterations in the plasma volume, and that the cell plasma ratio for minute vessels is lower than for large arteries, veins, or bleeding capillaries.

The serum-protein concentration fails to change in proportion to the alteration in the plasma volume. Madden and Whipple explain that the serum proteins are in a state of dynamic equilibrium and may easily enter or leave the blood stream according to the stimulus so that the concentration remains relatively stable.

The increase in the venous pressure in these cases may be explained either as a result of an increase in the local venous pressure due to an increase in the tissue pressure or as a result of an increase in the auricular pressure. The variability in the rise in venous pressure noted in these cases suggests that in some instances the factor of local obstruction may play an important role. In any event, the increase in the venous pressure noted in the antecubital vein would be associated with some increase in capillary stasis either local or generalized which would promote greater transudation of fluid from the capillaries into the interstitial tissues.

The considerable variation between the increase in plasma volume and increase in body weight noted after the first twenty-four hours on sodium bicarbonate compared to the more constant relationship in

forty-eight hours suggests that the equilibrium between the plasma volume and extracellular fluid disturbed by the addition of salt and water had not been re-established in twenty-four hours. The gain in plasma volume may be at first quickly lost to the extracellular fluid spaces. With increases in the amount of fluid in the interstitial spaces the tissue pressure will be increased and will result in a decrease in the amount of fluid leaving the capillaries. At the same time, protein is added to the blood so that the osmotic pressure in the capillaries does not significantly fall as a result of hemodilution, and the plasma volume may thus be maintained. If such a hypothesis be true it should be expected that considerable variations would be found in normal subjects according to the rate of absorption of water and salt, the rate of excretion, the volume of extracellular fluid, the tissue pressure, the capillary pressure, and the serum-protein concentration.

HENRY F. TURNER, M.D.

Turner O. E.: Investigation of Transfusion Reactions. *Pennsylvania M J* 944, 47, 1071.

Transfusion reactions are still prone to occur despite careful methods of establishing blood compatibility. In view of the complex array of blood constituents it is surprising that potential or actual reactions are not of more frequent occurrence.

In speaking of compatibility and blood groups, it must be assumed that the plasma contains two agglutinins (a and b) and that the erythrocytes contain two corresponding agglutinogens (A and B). The blood type depends on the agglutinin.

Some have been misled in thinking that as long as the donor and recipient are of the same blood grouping (O A B AB) a compatibility exists which is sufficient to avoid reactions from the transfusion of whole blood. Such a generality is not the case and more specific methods of determining compatibility must be employed.

The specific compatibility requirements of whole blood are:

1. Similar blood grouping of recipient and donor. The idea of the "universal donor" and the "universal recipient" is now obsolete but is occasionally used in unusual emergencies. It is now recognized that there are atypical agglutinins with subgroups of A and AB.

2. Careful cross-matching of donor and recipient. The donor's erythrocytes must be compatible with the recipient's serum, and the donor's serum with the recipient's erythrocytes.

3. The donor and recipient should be checked for Rh compatibility in routine transfusions. This can be done very simply by performing the Rh typing at the same time as the blood grouping.

4. Special tests should be made to rule out atypical cold and "warm" agglutinins.

The specific compatibility requirements of plasma are:

1. Pooled plasma, which is a careful combination of all types of plasma (O A B AB) mixed into

quantities of 2,000 cc. or larger, and preferably stored for thirty days under refrigeration. This material can be maintained in the liquid state for six months in the frozen state for three years and in the desiccated state indefinitely.

2. Type-specific plasma may be prepared but is usually not practical.

In any consideration of blood compatibility it is necessary to mention the practical application of the Rh factor. Investigations have recently shown that the Rh factor may produce hemolytic transfusion reactions, and that it has a relation to the cause of erythroblastosis in newborn infants.

It has been shown that 91 per cent of mothers of infants affected with erythroblastosis were Rh negative in contrast to the usual 14 per cent in the general population. Also the majority of the affected infants and their fathers were Rh positive. It is theorized that the Rh positive fetus stimulates the production of Rh agglutinins in the mother's blood, and that these isogglutinins from the maternal circulation traverse the placenta into the fetal circulation. In the fetus the anti-Rh or isogglutinins produce either hemolysis or suppression of the erythroblast maturation thus the name erythroblastosis foetalis.

The Rh factor therefore is of special clinical importance when blood transfusions are indicated for women and infants. Women who give a history of previous miscarriages and women who have borne children with erythroblastosis should always have a compatible Rh group-specific blood transfusion. In infants with erythroblastosis (baby usually Rh positive) a transfusion of Rh-positive, group-specific (or Group O) blood should be administered.

Transfusion reactions at the author's hospital have been investigated as to probable cause and a practical system of classification has been evolved.

Comparison of whole blood to plasma transfusion reactions for 1943 showed a per cent ratio of 7.5 per cent for whole blood to 1.2 per cent for whole plasma transfusions.

In the investigation of each blood transfusion reaction the final diagnosis of the recipient was obtained. In most cases the diagnosis was supported by clinical and laboratory data.

The following is a summary of the findings.

Thirty-seven per cent of the recipients had a diagnosis of malignant disease (carcinoma 27 per cent, miscellaneous 10 per cent).

Twenty per cent of the recipients had a diagnosis of thrombocytopenic purpura, bleeding peptic ulcer or pneumonia.

Forty-three per cent of the recipients had miscellaneous diagnoses.

In spite of the fact that donors were carefully selected and compatibility techniques were carefully watched, there remains the fact that a certain percentage of patients with a diagnosis of malignancy were prone to develop a blood transfusion reaction.

If blood transfusions are to continue in scientific popularity and to compete with the safety of pooled

plasma in transfusions improved methods of determining blood compatibility must be forthcoming.

STEPHEN A. ZEMAN, M.D.

Bradley W. H., Louth, J. P. and Maunsell, K.: Homologous-Serum Jaundice. *Bull. N. J.*, 1944, 2: 268.

The occurrence of jaundice in man after the administration of human blood products (plasma and serum) is now a well recognized phenomenon. This homologous-serum jaundice which is of hepatic origin is readily distinguished from the hemolytic icterus which may arise immediately after transfusion with incompatible blood or out-of-date stored blood. Clinically it is similar to, if not indistinguishable from epidemic hepatitis (catarrhal jaundice) but the incubation period is unusually long—commonly from two to three months in contradistinction to the twenty to forty-day period believed to occur in epidemic hepatitis.

A high incidence (57 per cent) of this jaundice has been observed by the authors among 71 subjects during the course of an investigation into allergic reactions to human serum. All of these subjects received pooled human serum from a single batch a few of them received in addition whole blood or serum from other batches. This batch was however the only common factor and was clearly incriminated as being icterogenic. Subsequently icterogenicity was confirmed by the results of the deliberate administration of this batch to 4 volunteer patients with rheumatoid arthritis in whom it was desired to produce jaundice for therapeutic reasons.

The dose of homologous serum administered varied from 0.1 to 1,200 cc. The attack rate was of the same order whether the serum had been given intradermally or intravenously and whether it had been given as a single dose or in repeated doses. The severity of hepatitis which in all cases was mild or moderate in degree only also appeared to be unrelated to the size the route or the frequency of injection. There was a suggestion however that the latent period was shorter when the material was given in the larger or in repeated doses. There is no evidence, so far, that permanent liver damage ensued. The incidence of jaundice was no greater in the allergic subjects than in the normal controls.

When the syndrome occurs after inoculation of measles convalescent serum or yellow fever vaccine it is relatively easy to detect icterogenic batches of material because in most instances serum from only a single batch has been given. When jaundice follows transfusion it may be impossible to decide which is the causative batch, because in the usual transfusion practice several batches of plasma or serum may be administered to a single patient and not infrequently whole blood is given as well.

In the authors series the clinical features and the biochemical findings were indistinguishable from those of epidemic hepatitis.

Ictericogenic batches of human serum and plasma cannot be detected by any laboratory or animal

tests. Their recognition is possible only when accurate records of the batch and bottle numbers of blood products given to patients are kept, and when a careful follow up of all recipients is practiced for some months afterward. JOSEPH K. NARAT, M.D.

Maunsell K.: Desensitization in Allergic Recipients after Serum Transfusions. *Brit. M. J.* 1944, 2 36

In the attempt to determine whether an allergic state in the recipient might not be an etiological factor in the development of allergic transfusion reaction, 53 patients whose ages ranged from eleven to forty three years, who gave positive skin reactions to one or more of the tested atopens (pollen dust, milk egg) and in whom reagins (Coca's atopy) were transferable to normal individuals (Coca's atopy) were tested with reconstituted dried pooled human serum and with auto- and iso-sera with intracutaneous injection and finally with repeated transfusions of the first cited serum.

In the intracutaneous tests all the high-grade positive reactions, and a great preponderance (77 per cent) of all the positive reactions were obtained in this group with the pooled serum (For details on the control groups please consult original article.) With the unpooled fresh sera it was found that the sera did not cause any more reactions when procured from atopic donors than when obtained from non-atopic individuals, but that as before reactors were in the main atopic recipients. No positive results were procured with iso-sera even among the atopics, and no influence on the results of the different blood groups was discoverable.

Among those given the test of transfusion, 17 were atopics and only 14 of these atopic individuals gave reactions. These reactions usually consisted of erythema from splotches to large confluent patches, raised wheals running together at times to form large white edematous zones these were preceded and accompanied by itching, running nose, streaming of the eyes, and tightness of the chest. Finally in a few cases there was a state of collapse (falling blood pressure and rapid pulse). In all attacks considered sufficiently grave adrenalin was given and it controlled the symptoms satisfactorily. Even the most severe attacks were over at the end of two hours. Rigor and rise of temperature occurred independently of the rashes.

Eleven of the 14 patients who reacted were retransfused two weeks later from the same serum pool and 10 showed definite signs of desensitization. Finally 7 of those who had developed an urticaria with the first transfusion were given a third transfusion again two weeks later and of these 5 did not react at all and 2 showed some erythematous areas, but not wheals. One boy eleven years of age, again developed a rash.

Maunsell concludes that the cause of the transfusion reaction lies in the recipient rather than in the donor in allergic cases, and that repeated transfusions result in a desensitization rather than a sensitization, of the recipient. However, in some cases, follow-up observations on these recipients revealed homologous serum jaundice, which discourages further attempts at desensitization of allergic patients with human serum at present in this country.

JOHN W. BUCKLEY, M.D.

SURGICAL TECHNIQUE

WAR SURGERY

Lowdon A G R : War Wounds of the Abdomen
Report of 64 Cases Treated by Laparotomy
Edinburgh M J 1944, 51 257

The author reports 64 cases all treated in a field surgical unit with the Eighth Army between El Alamein and Tunis and 19 cases treated during the Sicilian campaign. These cases are the only ones among a total of 744 battle casualties treated by operation on which he performed laparotomy and full records of the injuries and operations are given.

An operative mortality of 45.8 per cent among the whole series and more particularly of 44.0 per cent among the 25 patients with lesions of the colon appears to represent significant improvements over the results reported for the last war.

The methods of treatment are discussed and the improvement obtained is ascribed to the following measures:

- 1 Early and adequate resuscitation with intravenous infusions of blood and plasma.
- 2 The practice of exteriorization of damaged colon whenever practicable.
- 3 The intraperitoneal administration of sulfa diazine.
- 4 Immediate postoperative establishment of continuous gastric suction in all cases with peritonitis or intestinal lesions accompanied by adequate intravenous infusions of glucose-saline solutions.

HARRY W FINE, M D

Ross, K. C. and Ryan W P : Gas Gangrene at an Australian General Hospital in the Owen Stanley and Buna Gona Campaign *M J Austral* 1944, 2 35

From November 1 1942 to February 28 1943 there were 1,815 Australian battle casualties admitted to and treated at a general hospital. There were 82 patients with clinical gas gangrene and of this number 12 died. The patients arrived at the hospital from twelve hours to six weeks after being wounded. In 70 of the cases gangrene was obvious when the patient arrived at the hospital. The 3 other cases were believed to be examples of latent infection and they are described in detail.

In the first case a minor wound was excised in the hospital two days after the wound was received. Two days after operation a fulminating edematous gas infection developed and death ensued. In the second case the wound was partially excised in the field. Here some foreign material was removed through a new incision. The original wound looked clean but two days after the second operation a fulminating edema occurred and the patient died. In the third case a foreign body was removed from the wound and three days later this patient died from a fulminating edema.

A table showing the distribution of the wounds and the number of amputations and deaths is included. By far in most of the cases gas gangrene was confined to wounds in the buttock thigh leg and foot and shoulder and arm the forearm and hand amputation stumps and the trunk showed considerably less. In some of the cases there were multiple anatomical parts involved.

The diagnosis was made from the typical stench the appearance of the tissues the presence of gas in the wound the demonstration of gas in the tissues the presence of anaerobic clostridia in wound culture, and by means of x rays.

The diagnostic points suggested as being quite important are discomfort and peevishness after operation rapidity and threadiness of the pulse intense and rapidly recurring anemia and icterus.

Clinically the cases showed a wide range, from a local abscess to widespread fulminating edema. In 3 patients there was little evidence of infection in the wound itself but an acute overwhelming cellulitis spreading from the wound commenced four or five days after the wound was received.

The bacteriological findings showed an anaerobic clostridia in 48 of the 51 cases cultured. The clostridium welchii was present in 30 cases.

All patients with gas gangrene were given a full course of 35 gm. of sulfanilamide 6 gm per day were administered until the course was completed. Sulfanilamide powder also was dusted into the wound. Gas-gangrene antitoxin was administered to 51 patients in dosages of from 20,000 to 200,000 units. Forty patients received transfusions of blood and plasma (1 liter of blood and 1 liter of plasma).

The authors soon learned to rely more and more on radical excision no matter how old the wound was. Drainage is of paramount importance and it must be remembered that fluid runs downhill. At the completion of the operation the wound was cleansed with hydrogen peroxide and saline solution and dusted with powdered sulfanilamide. Then it was filled with vaseline and covered with vaseline gauze. The extremity was then enclosed in soft dressings or plaster. X ray therapy was given in adequate doses to 1 patient only this patient proceeded to a fatal termination.

RICHARD J BENNETT JR. M D

Blood Transfusion during the Battle of Maroth
with Special Reference to Problems of Supply
J R Army M Corps 1944 83 7

This article discusses the problem of supply maintenance and distribution of blood transfusion stores under battle conditions beginning with the El Alamein campaign. The plan originated with a Base Transfusion Unit which was responsible for all supplies of apparatus and fluids. It, moreover, was responsible for preparing and supplying intravenous and intraperitoneal sulfonamides.

During battle excluding whole blood the quantity of stores required by a corps area approximated $\frac{1}{4}$ tons a day. One hundred twenty bottles of blood per corps per day was required at the beginning of a battle. A separate unit maintained the supply between the base and the forward area and the main supply section was located at an Advanced Air Transport Center.

During periods of calm, the Forward Supply Unit kept its refrigerator half full of blood. Seven days before battle 100 bottles a day were flown in until it was fully stocked which usually meant over 800 pints. In addition stocks of plasma serum and saline and sulfonamide preparations were augmented. The Advance Blood Bank was situated 5 miles behind the front line whereas the Main Supply Section was about 30 miles behind.

As soon as serious resistance was encountered one Field Ambulance opened out as a Surgical Center and a landing strip was prepared close to it for the evacuation of casualties by air. Transfusion stores were carried back and forth from the Main Supply Section by ambulance planes.

STEPHEN A. ZIEGLER, M.D.

Code S: War Surgery in the Royal Air Force. *Brit J Surg* 1944, 3

Excluding major catastrophes, such as collisions in midair, power dives to earth or into the sea, and the burning of the plane in air where death is instantaneous or occurs within a few hours, and exclusive of fractures (mentioned only in connection with discussions of organization of the services) the conditions arising in connection with the operations of the R.A.F. which require surgical aid are burns, wounds, frost-bite, immersion injuries, and head injuries.

The burns typically coming to treatment in the R.A.F. are relatively small in extent, localized to the hands and face, and of second or third degree. They are largely left alone at first, but provision is made for warmth (wrapping up), oxygen, morphia, plasma and vaseline or antburn jelly (3 per cent sulfonamide in a water-soluble base). For hand burns the Stannard glove, containing weighed amounts of one of the sulfonamides, may be applied at once. Later there is instituted either the closed method with tannic acid or other coagulant, or in burns of the face, hands, genitals and perineum, the "open method" with vaseline-gauze, tulle grass, saline packs, and C.T.A.B. in lanette wax, and with local application of sulfonamides. Early skin grafting and the institution of preferably active motion or at least fixation of the hand in the functionally correct position, are important. Penicillin is mentioned enthusiastically.

Wounds in the R.A.F. are classified into multiple foreign-body injuries in which healing is perfect and return to duty is permitted without the attempt to remove all of the embedded fragments, flak injuries, machine-gun bullets, cannon shell, and hand grenade and bomb explosion products. In these cases severe

injuries seem to predominate, ranging in gravity all the way up to cases in which whole parts of the body are blown away or must be immediately amputated, and in which resuscitation itself becomes a major problem. However by means of early surgical attention, a more generous use of immobilization with plaster casts, chemotherapy (penicillin seems likely to alter the established principles for the treatment of war wounds), conservative excision, adequate drainage and early rehabilitation, some surprising recoveries have been attained. In the air force amputations are delayed when possible, as the injuries are so apt to be multiple.

Seventy-five per cent of the cases of frostbite in air-crews are mild and recover rapidly. In most cases exposure of the affected part was deliberate and careless mechanical failure of the oxygen supply or of the heating accounted for some of the cases. Remarkable reduction in the incidence of frostbite in the air-crews, amounting to virtual abolition, has been achieved gradually by preventive measures, education, and technical improvements. Recent experience in the R.A.F. supports the view that elevation of the limb, avoidance of trauma, and cooling of the affected parts lead to the minimal loss of tissue. Cooling of the frostbitten part can be achieved by means of ice packs, a stream of cold air from a fan, or iced saline packs. Better still, however by simple exposure to room temperature.

In immersions the injury sustained depends upon the temperature of the water, the length of time of exposure, and the associated trauma; however there is usually added the general effects of exposure, and concomitant shock. The feet, ankles, and legs are the parts most commonly involved. Treatment consists in general measures to combat shock, elevation of the affected limbs, cooling by exposure to room temperature and surgical cleanliness.

A study of head injuries sustained in flying in members of air-crews reveals some interesting points, during the first two years of the war 1,515 cases were recorded. Head injuries alone or in association with other perhaps multiple injuries, but without maxillofacial involvement, accounted for 75 per cent of these patients. Maxillofacial injuries, on the other hand, were relatively rare, accounting for only 16.6 of the total of 1,545 injured. The combination of head and maxillofacial injuries was equally small, comprising 16.6 of a total of 748 survivors. None of the maxillofacial injuries proved fatal. On the whole the heaviest mortality has been in cases of skull fracture, especially when complicated by other injuries; however of the patients who survive the immediate effects, about 74 per cent are returned to flying duties, the majority within a period of two months or less. These results compare favorably with the end results of other injuries.

On the whole the advances made in the treatment of injuries of all kinds, as sustained by fliers, seem due to provision for the earliest and best possible treatment. Facilities provided by the Royal Air Force for its air-crews in special surgical depart-

ments for injuries resulting from flying and from enemy action exceed even those of teaching hospitals in peacetime. The final aim and object is to obtain the maximum operational efficiency in the shortest possible time. JOHN W. HAYNSMAN, M.D.

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

May 11: Closure of Defects of the Lips with Composite Vermilion Border-lined Flaps. *Surg.* 1944 130 214.

Defects of the lips not suitable for direct closure may be repaired by the rotation of composite vermillion border-lined flaps. Vertical lip defects may be repaired in accordance with the principles of Eastlander's operation which is particularly adaptable for closure of triangular defects of the lower lip. The flap is pedicled and contains the coronary artery. To overcome vertical shortness and to enable full opening of the mouth, an additional operation is necessary. This requires the switching of triangular flaps. Defects of the lower lip and chin are best repaired when they appear triangular in form (Burrow) or heart-shaped (Dieffenbach). Triangles of skin and muscle are excised from the nasolabial region with the base of the triangle in line with the vermillion border. The mucous-membrane floor is incised and, if necessary, turned outward to lengthen the vermillion border. The cheek flaps are mobilized by means of an incision along the gingiva buccal sulcus which is carried to the anterior border of the masseter muscle. These flaps are then anchored into

Fig. 2. a Triangular defect of the lower lip not larger than one-half the width of the lip. The defect includes the lower border of the left corner of the mouth. To close the defect, a vermillion border-lined flap is to be rotated from the upper lip and the nasolabial region. The pedicle of the flap containing the coronary artery is to replace the corner of the mouth. The flap should be made one-half as wide as the defect in order to shorten the upper and lower lips proportionately. b The flap is rotated into the defect. The secondary defect is closed by suturing the wound edges together.

Fig. 3. a Reconstruction of corner of the mouth in those cases in which the pedicle of the flap (Fig. 1) forms the new corner of the mouth. The vertical shortness is overcome by switching triangular flaps. Flap (a) is exchanged with flap (c) with flap (b). Thus not only the oral orifice is widened, but a more natural corner of the mouth is achieved (Courtesy of J. B. Lippincott Co.).

position with oblique sutures to the gums. This is followed by closure of the triangles in layers, formation of the vermillion border and connection of the flaps in the midline. Finally the wound is drained from the lower vertical edge.

Large irregular defects involving the entire lower lip and chin are best closed by means of lined flaps from other parts of the body. If the defect can be made triangular, a modification of Dieffenbach's operation is recommended.

BENJAMIN G. P. SHAPIROFF, M.D.

Young, P. and Pavata, B. V.: Suture of Wounds by Plasma Thrombin Adhesion. *Br. J. Med. Chik.* 1944 6 80.

This report is an evaluation of the efficiency of plasma clot as a means of artificially producing rapid adhesion of wound surfaces. The method has been used in traumatic lacerations in which there is little or no tension on the wound edges as a skin suture in clean surgical incisions to promote adhesion when large wound surfaces are in contact, as in radical mastectomy and as a means of fixation of free skin grafts.

This method is a simulation of the normal process of wound healing. The formation of fibrin occurs early in clean wound healing. The fibrin acts as a binding agent between the wound surfaces.

Over a period of years various investigators have studied the use of plasma clot as a suture material. It has been found effective but to have less tensile strength than the usual fine sutures of silk or surgical

gut in common use. The main disadvantage when the plasma was allowed to clot spontaneously or when this action was accelerated by various tissue extracts was the slow formation of the clot. Consequently progress has been made in the purification and isolation of thrombin and through its use rapid clotting of plasma can be obtained. In fact the speed of clot formation can be adjusted as desired by varying the concentration of thrombin used. Moreover, since thrombin was found to be nontoxic when applied to the surfaces of wounds, it can be safely used for fibrin suture.

The artificial formation of fibrin in wounds is simple. The surfaces of the wound are first flushed with plasma. It is not necessary that the plasma be autologous. The plasma used has been the stock pooled plasma from a plasma bank. Excess is avoided since this will result in a gelatinous mass of clot which on contraction releases an undesirable amount of fluid.

After plasma has been evenly distributed over the wound surfaces, thrombin solution of the desired concentration is sprayed on the wound with syringe and needle. The surfaces of the wound are quickly adjusted and held in apposition steadily and evenly for about two minutes or for a period of about twice as long as is necessary for fibrin to form from the solution of the strength being used. It is important to realize that any movement of the wound surfaces or edges during this part of the procedure will result in failure of adhesion. Time must be given for the thorough precipitation of fibrin and its attachment to the wound surfaces. As previously mentioned the tensile strength of plasma clot is not great. After a few minutes have elapsed for fibrin formation one can exert moderate pull on the wound without the occurrence of separation. If greater pull is exerted, one can see the fibrin strands stretch and finally rupture. It is therefore usually advisable to support wounds sutured in this manner by compression dressings and to prevent motion for a few days. Motion should not be allowed too soon since the healing process can be disrupted even up to fourteen days.

Adherence of wound edges or surfaces can be readily accomplished by the use of plasma and purified thrombin. The fibrin fixation artificially produced in this way has less tensile strength than ordinary suture material for this reason use of plasma-thrombin adhesion of wounds should be limited to those wounds in which tension does not exert.

Plasma thrombin adhesion has been found useful (1) as the sole fixation for traumatic lacerations (2) as a skin closure where a particularly fine scar is desired (3) as a method of producing adhesion between the flaps and the chest wall in radical mastectomy and (4) as an adjunct in free skin grafting.

No untoward results have been observed in 60 cases in which the plasma-thrombin method of adhesion of wounds has been used.

JOHN L. KIRKPATRICK, M.D.

Collier F. A., Crook, C. E. and Job, V.: Blood Loss in Surgical Operations; Chairman Address. *J. Am. M. Ass.* 1944 86 1

The amount of blood lost during surgical operations of various types has been measured and reported by a number of observers. The facts disclosed by these observations have not been generally recognized nor has their practical importance been sufficiently emphasized. In order to bring attention to this technical problem, the literature on it has been reviewed and further studies have been made and are here reported. Shock appearing during and after operation is still the apprehension of the surgeon and a menace to the patient. During the past three years an enormous amount of investigation on the subject of shock has added materially to our knowledge of it. One fact, however, remains clear there is no single reliable test or clinical sign of impending shock especially in anesthetic and postanesthetic state. By the time shock is recognized as such it is well established. Our ability to treat shock has improved but it is far from satisfactory. The earlier the treatment is instituted the better the results, and if its advent is anticipated it may be prevented far easier than it may be cured. Though there are no positive early tests of impending shock there is a large body of ground of clinical observation from which to deduce that shock will appear under certain circumstances—burns involving 30 per cent or more of the body surface, severe dehydration, multiple fractures or wounds, crushing injuries, exposure to cold air or immersion in cold water and extensive blood loss. It is well known that shock develops more readily after a given injury if there exists malnutrition or starvation, anemia, dehydration, physical or mental exhaustion, chronic illness, or prolonged bed rest. With these facts available, one should be able to anticipate and usually prevent shock in the surgeon in civilian hospitals.

In 1924 Gatch and Little reported the first study of blood loss during some of the more common operations in general surgery in which accurate measurements of the losses were made. They pointed out that the amount of blood lost in the ordinary laparotomy is not great but that in operations involving extensive dissection the loss may be excessive. They concluded that a patient in fairly good physical condition could lose from 600 to 700 cc. of blood without any apparent harmful effect on the postoperative course. Likewise an adult in good health does not manifest any serious effect from hemorrhage until the amount of blood lost is between 800 and 1,000 cc. Alexander Blain in 1929, in commenting on his experience with 3,000 transfusions, stated that the amount of blood lost at operation is often several times greater than that estimated by the surgeon. He urged the preoperative correction of anemia and the immediate replacement of blood lost during operation and condemned delay in giving blood transfusions until after shock had developed. Collier and Maddock in 1932 measured blood loss during some of the ordinary operations and con-

cluded that the amount of blood lost is always greater than the surgeon estimates. Windfeldt in 1937 made direct measurements of blood loss during operations and concluded that the loss is often far greater than supposed so that without appearing dangerous it may reduce the volume of the circulating blood considerably. Determination of hemoglobin concentrations before and after operation did not give quantitative information regarding the amount of blood lost. Pilcher and Sheard in 1937 estimated the blood loss by a photometric method and found that the average loss from prostatic resections was 49 cc. This finding stimulated efforts to secure better hemostasis and in a second series studied after alterations were made in the technique, the average loss was reduced to 391 cc. A group of 49 general surgical cases was studied for comparison. Hubby in 1937 used this method to determine the hemostatic effect of congo red. White, Whitlaw, Sweet and Hurwitt in 1938 made an exhaustive study of blood loss in neurosurgical operations. They found that in the course of extensive intracranial operations the average loss was from 500 to 1,500 cc. They concluded that these patients rarely develop the typical shock state unless the loss is over 1,200 cc. or unless the loss is rapid. They urged greater attention to hemostasis at the expense of time and advocated discontinuance of the operation if the loss exceeded 1,200 to 1,500 cc. Stewart and Rourke in 1938 studied changes in the blood and interstitial fluid resulting from surgical operation and ether anesthesia. They pointed out that the hematocrit changes induced by trauma and blood loss of operation are not proportional to the blood loss and that the structurally important elements of blood plasma, that is, protein, sodium and chloride are accurately sustained by the body. They emphasized the fallacy of assuming a quantitative relationship between the changes in the concentration of hemoglobin or plasma protein and changes in the plasma volume.

Leriche and Vasilaros in 1939 reported measurements of the blood loss in 29 operations of diverse character. They concluded that a loss even as small as 500 cc. of blood is not a matter of indifference to a body which is called on to effect the repair of trauma and disease. Nesbit and Conger in 1941 measured the blood loss associated with transurethral prostatectomy and stated that this determination is easily carried out at the time of operation and should be made a routine procedure so that untoward blood losses may be immediately appreciated and corrected by transfusion. They urge the use of whole blood to replace the blood loss accurately. Wangenstein in 1942 described a gravimetric method for determining the status of hydration and blood loss during operation. He advocated the replacement of minor blood loss by an amount of plasma from 100 to 200 cc. greater than the blood lost, or if the loss is excessive it should be replaced by whole blood. He found the average blood loss from gastric resection to be from 300 to 500 cc. In 1942 Buxton and White measured the blood loss in 109 patients

undergoing operations on and in the thorax. The loss in these operations was exceptionally large, averaging about 700 cc. for each stage thoracoplasty, 1,600 cc. in lobectomy, and about the same for pneumonectomy. Large transfusions during operation were advised. Oppenheim, Pack, Abels and Rhoads in 1944 measured the amounts of blood lost in various abdominal operations and described a simplified method for carrying out this technique. The amount of blood lost was not excessive. However they believed that a transfusion of from 500 to 600 cc. of blood during the operation is of great benefit to patients operated on for cancer of the gastrointestinal tract. They advised the routine determination of blood loss, especially in elderly patients with cardiovascular insufficiency in order to prevent the administration of unnecessarily large amounts of fluid.

In table I in the original article are shown the blood losses from 626 operations collected from the data of these authors. The cases are grouped according to the types of operation and the maximal minimal and average losses are given. It was the unanimous conclusion of all who studied this problem that the blood losses in nearly every operation were greater than expected by the surgeon. The constant ooze of blood from large vascular fields leads to a large loss of which the surgeon is frequently not cognizant. Accurate measurement of blood loss leads to an appreciation of the importance of better hemostasis. Nevertheless at times in spite of every effort at hemostasis the loss will still be large and transfusions should be planned in advance.

Analysis of the literature impresses one with the fact that not enough emphasis has been placed on the relation of the amount of blood lost to the total blood volume. Since the blood volume varies with the weight of the patient, it makes a vital difference whether a given amount of blood is lost from a large adult or from a small child. In table 2 are shown some figures illustrating the relationship of a 100 cc. blood loss to the blood volume in patients of differing weights. Blood comprises 77.7 cc. per kgm. of body weight in the male and 66.1 cc. per kgm. in the female. For all practical purposes one thirteenth of the body weight is blood and cells make up 45 per cent of the blood volume in men and 40 per cent in women. A simple method of calculating blood volume is to allow 30 cc. of blood for every pound or 75 cc. for each kilogram of body weight. Stewart and Rourke showed blood loss in terms of percentage of total blood volume but did not comment on its critical relation to weight. Nadal pointed out the important relationship between the size of the patient and the amount of blood that could be lost before signs of shock would appear.

Since several of the preceding studies were carried out in the University Hospital, Ann Arbor, Michigan, the surgical staff has come to realize the importance of a knowledge of blood loss during operation. Further investigations have been made to stress the necessity of admitting that blood will be

lost that its approximate amount should be known and that it should be replaced by blood. Fifty cases were studied and 42 have been selected for presentation. The method used for determining blood loss was essentially that of Gatch and Little with the following exceptions:

1. Oxyhemoglobin was measured in the Evelyn photoelectric colorimeter.

2. The fluid from aspirator bottle instrument and glove washings was kept separate from the washtub fluid.

3. The sample from the 50 liters of washtub fluid was taken directly from the washtub before the drapes and gauze sponges were removed. Controlled washings with known amounts of blood on sample outfits of drapes and sponges yielded an average recovery of 95 per cent. The detailed method was as follows:

With Evelyn's method oxyhemoglobin was determined on the solution containing equal volumes of the following fractions:

1. Fluid from drapes and sponges extracted in washing machine in 50 liters of distilled water for two hours.

2. Aspirated fluid and water used to wash instruments and gloves diluted to 5 liters or to 10 liters if necessary and finally diluted 1:10 or 1:5 with distilled water. The solution was centrifuged to clarify it and diluted 1:1 with distilled water.

The patient's preoperative concentration of hemoglobin was determined at the same time.

Calculations

Gm. Hb lost = C m % Hb from blood curve $\times \frac{1,000}{250}$

$\frac{\text{Hb lost}}{\text{pt's. preop. Hb}} \times 100 = \text{cc. blood lost}$

The cases here presented were selected for study on the basis that because of their character a high blood loss might be expected, and that they were limited chiefly to five categories to facilitate comparison. Particular interest was centered in changes in the blood picture associated with hemorrhage. Therefore many patients whose blood loss was minimal were excluded from the presentation. Consequently the blood loss in these groups does not represent average results from routine operations of their types. The operations were performed by ten surgeons from the resident staff.

In tables 3 to 8 are shown measured blood loss and its percentage of total blood volume. Intravenous solutions given in the operating room, blood transfusions given during or immediately after operation, and the degree of hypotension stated in terms of 1 to 4 plus in patients during various types of operation. In table 3 the blood loss from radical mastectomy is slightly higher than found by others but, since these operations are always accompanied by such losses, transfusion during these operations has been made a routine at the University Hospital by the staff. Patient 27 developed a moderate hypotension which was corrected by transfusion of blood equal in

amount to the loss. In table 4 the blood loss associated with thyroidectomy is shown. These patients all presented large recurrent, or unusually large goiters and the average blood loss was much higher than found in routine thyroidectomies. In 12 instances the loss was above 25 per cent of the blood volume but the surgeon realized this fact and replaced the lost blood by transfusion during the operation.

In table 5 is shown a group of patients presenting difficult technical problems in surgery of the biliary tract. Many had been operated on previously. The majority were jaundiced and in all the common duct was explored or reconstructed. The operations were long and the blood loss averaged nearly 600 cc. Case 41 is of interest since the blood loss of 1,065 cc. represented 41 per cent of the blood volume; the patient was emaciated and weighed only 46 pounds (39 kgm.). This patient developed an alarming shock state from the operative trauma, blood loss, and bile peritonitis, and was given 3,000 cc. of blood in the next forty-eight hours after which convalescence was relatively uneventful. Contrast this 41 per cent loss with that of case 21 in which a larger amount of blood, 1,455 cc., was lost, the latter amount representing only 27 per cent of the total blood volume. Both cases required extensive replacement by blood. In operations of this character performed on undernourished and jaundiced patients one should always plan on adequate replacement of the blood loss. The routine immediate replacement of blood in these patients was found to be inadequate at the time of the study and the authors have since planned for a liter of blood to be given during operation.

Table 6 presents studies of blood loss in 12 cases of cancer of the rectum treated by a single stage abdominal perineal resection. The losses in this group averaged 410 cc., the principal loss resulting from the perineal dissection. While this loss is not great it should always be replaced by blood as so many of these patients are malnourished, anemic, and dehydrated (Miles regimen). The occurrence of hypotension in these patients (case 26) was thought to be of anesthetic origin. Table 7 presents 3 complicated gastric resections accompanied by a blood loss averaging 600 cc. In table 8 is shown the relatively large losses resulting from operation in which large body surfaces are opened. This blood loss is from multiple small rather than from single large vessels. The use of gauze packs as hemostatic agents tends to obscure hemorrhage rather than control it. Table 3 is a similar example of operations on large body surfaces.

Concurrently with the blood-loss determinations, observations were made of changes in hematocrit and hemoglobin and plasma protein concentration before and after operation. These findings are listed in relation to blood loss in table 9 and deductions from them agree with those of Stewart and Rowntree. There was found no correlation between the amount of blood lost and the simultaneous changes in hematocrit, hemoglobin, and concentration of plasma

protein immediately before and following operation.

These determinations therefore cannot be used to estimate the need for blood volume replacement during and after operation. Obviously, it follows that if one wishes to know the amount of blood lost in any operation one must depend on direct measurement. This approach is not often practical, in which event one must rely primarily on a knowledge of average losses to provide a basis for the replacement of blood loss during operation. Additional blood may be given if the clinical state of the individual demands it.

The authors believe that even minimal blood loss retards convalescence; that all loss over 300 cc. in healthy adults should be replaced; and that all blood loss in operations on aged, undernourished, seriously ill, or bedfast patients should be replaced with equal quantities of blood.

JOHN J. MALONEY, M.D.

McClure, R. D., Warren, K. W., and Fallis, L. S.
Intravenous Pectin Solution in the Prophylaxis and Treatment of Shock. *Canad. M. Ass. J.* 1944, 51, 206.

Pectin solution was administered intravenously as a blood substitute to 275 patients. In the majority of cases it was given prophylactically during some major surgical procedure on the gastrointestinal tract. All solutions were carefully prepared by the method of Hartman and were tested for osmotic pressure, viscosity, specific gravity, and pH. The importance of carefully controlled preparation of the solution is emphasized. The amount of solution administered varied between 200 and 1,600 cc. with the most frequent dose being 800 cc. Results were evaluated by the course of the blood pressure and pulse during operation and by the presence or absence of shock postoperatively. Measured by these standards the results were good in 75 per cent, fair in 20 per cent and poor in 5 per cent of the patients.

The untoward effects of pectin administration are discussed. Rouleaux formation follows and persists for at least twenty-four hours but causes no detectable symptoms. The sedimentation rate rises in all cases. Only 2 patients in a series of over 300 manifested any evidence of reaction. Purpura was not observed with dosages suitable for the prophylaxis of shock, although it occurred following large daily doses for other purposes. Tissue deposition has been reported following the administration of more than 4,000 cc. of commercially prepared pectin.

It is concluded that pectin, though inferior to blood or plasma, appears to be of more value than glucose or saline solution in the prophylaxis of shock in extensive surgical procedures. It is nontoxic and nonantigenic in quantities of from 1,000 to 1,500 cc., which are usually required to maintain the blood pressure in the presence of shock-producing conditions. Untoward effects appear only after the intravenous injection of amounts in excess of 4,000 cc.

JOHN L. LINDQUIST, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Byrne, J. J.: Grease-Gun Injuries. *J. Am. M. Ass.* 1944, 135, 405.

A case presented by Smith is discussed in which grease was accidentally injected into the base of the left index finger under 7,000 pounds of pressure. The subsequent course is followed. Two cases reported by Brooke and Rooke and 2 cases reported by Mason and Queen are abstracted in this article.

The author presents the case of a man who accidentally had grease injected into his left 4th finger. The subsequent clinical and laboratory findings are presented and discussed very fully and practically a day-by-day follow-up of the case is given. The author believes that pressure, chemical irritation of the grease, and secondary infection are the three factors which may devitalize tissue in the acute phase of this type of injury. If the original pressure does not cause irreparable damage, the grease may act further as an irritant and set up subsequent acute reactions. In the chronic phase of these injuries, most of the grease is encapsulated in chronic inflammatory tissue or may be slowly removed by phagocytosis. Encapsulated grease may not remain inert in the tissue but may cause a formation of tumors. Microscopic examination of these tumors reveals whorls of fibroblasts with foam cells, plasma cells, polymorphonuclear cells, and some lymphocytes, monocytes, and giant cells.

The best treatment is prophylactic. Once an injury has occurred, expectant and conservative treatment should be followed in the form of bed rest, sedation, and massive dressings at room temperature. No hot dressings should be used as this may lead to gangrene. Longitudinal incisions are of doubtful value in removing the widespread grease. Surgery should be limited to the removal of sloughing tissue and/or incision of fluctuant areas when abscesses develop. Early amputation is not recommended. A general anesthetic is recommended. Procaine digital block is condemned. Subcutaneous oleomas should be removed under a general anesthetic in a bloodless field. When overlying skin is involved, it should be sacrificed and the resultant defect repaired with free or pedicled skin grafts.

RICHARD J. BENNETT, JR., M.D.

Dingwall, J. A., III., and Andrus, W. DeW.: A Comparison of Various Types of Local Treatment in a Controlled Series of Experimental Burns in Human Volunteers. *Ann. Surg.* 1944, 120, 377.

In order to evaluate the efficacy of 12 different local treatments of burns, the authors have produced 82 bilateral, symmetrical burns in 41 human volunteers with the use of a simple apparatus consisting of a hollow metal plate of almost exactly 10 square centimeters of area through which live steam is passed. When such a device of constant temperature and area is applied to symmetrical points on the anterior

a part of the thigh for the same length of time as determined by an electric timer by which tenths of second were easily measured the resulting burns should be very nearly alike in every way including depth. As proved by biopsy the fluorescein test and by the nature of the subsequent healing process of uncomplicated lesions these areas were deep second degree burns. Without fail all lesions showed vesiculation in twenty-four hours.

For the twenty-four hours following the production of these lesions dry sterile gauze was used as a covering, it was secured by adhesive tape and completely closed the areas. The twenty-four hour delay before the administration of definite therapy was chosen in order to stimulate accidental burns since these were frequently seen after some time had elapsed. Following removal of the initial dressing, all vesicles were opened under sterile technique and the areas were debrided in the majority of instances. Routine cultures were taken at this time. One burn was then selected at random for definite therapy with one agent and the contralateral area was used as a control, a different therapeutic preparation being employed.

The result of the following treatments were studied: sulfafilm control film (without sulfonamides) tannic acid boric acid ointment, boric acid ointment combined with the oral administration of sulfadiazine triple dye vaselined gauze triethanol amine sulfadiazine with methocel penicillin ointment fibrin film and sulfadiazine gelatin.

The best results as measured by the rapidity of healing absence of symptoms and freedom from all complications were encountered in the group treated with a sulfonamide-impregnated plastic film. The next best method of treatment, which was very nearly as efficacious was the local administration of a bland ointment combined with the oral administration of sulfonamides.

The value of the use of the sulfonamides either locally or systemically was clearly demonstrated in the control of infection while the evidence of sensitivity resulting from their local application was minimal, and believed to be of no practical significance.

The importance of restricting the frequency of dressings was confirmed as there was a direct relationship between the rate of healing and the number of times the dressings were removed. Under the conditions of the experimental series the lesions which were not debrided healed as well and as rapidly as those from which all nonviable tissue was carefully removed.

The authors' experience in this series of experimental burns gives additional evidence for the abandonment of any type of treatment with escharotic agents.

The authors suggest that so-called second-degree burns should be carefully described as to their depth to facilitate greater accuracy in comparing the results obtained in series reported in the literature.

JOSEPH K. NARAY, M.D.

Gardiner, R. H.: Intraperitoneal Chemotherapy. *Br J Surg* 34: 37-49.

No method of effectively combating peritonitis by a direct attack had been devised before the introduction of the sulfonamide drugs which are successful in a large majority of cases if used intraperitoneally. Diversity of bacterial flora and the presence of a large quantity of free pus interfere with the action of the sulfonamides in peritonitis.

Sulfanilamide and sulfapyridine appear to be the drugs of choice and sulfapyridine shows the slowest absorption rate and the lowest toxicity of any so far employed. On the average, 15 gm. is the dose of the sterilized powder recommended, but 25 gm. or more may be inserted if profuse suppuration is present.

Contaminated wounds treated with an emulsion of sulfonamide powders will heal by first intention in the large majority of cases.

Intraperitoneal chemotherapy should now be included in the armamentarium of all emergency surgeons. This is borne out by the reports showing a fall in the mortality rate of appendicitis and its complications, and other acute abdominal conditions when it is employed.

Encouraging results appear to accrue from its use in intestinal obstruction necessitating bowel resection but further investigation is necessary.

The whole course of large bowel surgery may be altered by the use of intraperitoneal chemotherapy and the axial anastomosis become a safe method and the one of choice for the reconstitution of bowel continuity. Care in diagnosis, preoperative and postoperative treatment and technique is essential, and chemotherapy is only an adjunct to these.

HOWARD A. MCKENRY, M.D.

Ellis, F. A.: The Potential Danger of the Topical Use of Sulfathiazole; Report of 16 Cases of Sensitization to Sulfathiazole. *Sent. M J* 1944 37: 493.

Within the last year Ellis has seen 16 patients who were thought to be sensitive to sulfathiazole locally or internally. Fifteen gave positive patch tests to sulfathiazole ointment and 1 was not tested because the generalized eruption did not clear up sufficiently before the patient was lost from observation. 7 patients developed a generalized dermatitis immediately following the ingestion of sulfathiazole. Later 1 took sulfadiazine without difficulty.

It has been suggested that sulfathiazole ointment should not be used for more than five days and that the use of this ointment in eczematous eruptions without infection is of no value but is prone to sensitize the patient to sulfathiazole. The local use of sulfonamides may sensitize the individual and perhaps later preclude internal sulfonamide therapy in far graver diseases. This form of medication should be used only for short periods and then only when there is an active pyogenic or other infection which is known to respond to local sulfathiazole therapy.

There is some evidence that a vehicle containing lanolin or cholesterol compounds may increase the

possibility of sensitization to sulfathiazole and to the base. The use of band-aids impregnated with sulfathiazole as recommended by several reliable pharmaceutical firms may cause more harm than good. The local use of proprietary medicaments containing the sulfonamides is also dangerous and should be prohibited. Intranasal therapy with solutions of sulfathiazole may sensitize the patient.

J M MOXA, M.D

Kirby W M., and Hepp V E.: Treatment of Osteomyelitis of the Facial Bones with Penicillin. *J Am Med Ass* 1944, 125 1019

In spite of sulfonamide therapy osteomyelitis of the facial bones either as a postoperative complication or as an extension from diseased sinuses results in a mortality of 80 per cent particularly when there is associated infection of the brain and meninges.

After seeing a small series of cases the author recommends that the patients be treated exclusively with penicillin for a period of from three to four weeks until sequestration of the devitalized bone is complete. Prolonged treatment with larger doses of penicillin is more effective than treatment with smaller doses which was usually followed by relapses. The dosage of penicillin recommended is 500,000 units daily given by continuous intravenous drip for from ten to fourteen days. Thereafter 15,000 units are administered intramuscularly every three hours for from fourteen to twenty-one days. The sequestra are then removed surgically and penicillin therapy is continued for seven postoperative days.

The organisms responsible for the osteomyelitis of the facial bones in this series were the anaerobic non hemolytic streptococci and the coagulase positive staphylococcus aureus. This combination of penicillin therapy and surgery appeared to cause a drastic reduction of the mortality rate.

BENJAMIN G P SHAFIROFF M.D

Jeffrey J S., and Thomson S.: Penicillin in Battle Casualties. *Brit Med J* 1944, 2 1

This report summarizes the effect of penicillin in the treatment of soldiers wounded on the Italian front from January to June 1944. Penicillin was used at a few selected forward stations in the forward area. In place of sulfanilamide a mixture of penicillin-sulfathiazole powder (5 000 units of penicillin per gram of sulfathiazole) was insufflated into the wound. The recognized surgical principles of wound treatment were in no way abandoned.

In one series of cases 50 per cent of the debrided wounds insufflated with penicillin showed no growth on culture at the base five days later. The technique of penicillin insufflation varied with the nature of the wound. Dirty superficial wounds received one daily insufflation for two days and were then sutured on the third day after frosting with the powder mixture. Perforating wounds were sutured with fine rubber tubes leading down into the sinus and 3 cc. of penicillin (250 units per cubic centimeter) were instilled through each tube for four days.

One base hospital reported that there were no failures when 110 superficial wounds were sutured and given one insufflation of penicillin sulfathiazole powder. From the same hospital failures were reported in 23 per cent of 68 superficial wounds sutured after the application of sulfanilamide.

Twenty five cases of large shell wounds of the buttocks or thighs were treated by suture and drainage tubes through which insufflations were made. As a result of this form of treatment, 70 per cent of the wounds healed in ten days. Previously the healing time was at least forty days.

Penicillin was found to be of great value in the management of hemothorax or empyema. For these conditions local instillations into the pleural cavity were essential because systemically the penicillin did not get through the pleural barrier in sufficient concentration. If the treatment consisted of aspiration alone 60,000 units of penicillin dissolved in from 30 to 60 cc. of water were instilled at the end of aspiration. With this method of treatment the incidence of rib-resection operations for empyema decreased.

Gas gangrene which usually resulted in a 50 per cent mortality was reduced to 25 per cent when penicillin was used in combination with surgery and antiserum. Penicillin was also found to be superior to the sulfonamides in the treatment of head wounds involving the scalp and brain. It was not used in the treatment of penetrating wounds of the abdomen because it was believed that physiological causes were responsible for the high percentage of deaths rather than infection.

BENJAMIN G P SHAFIROFF M.D

Hepl, M., Ochauer A. and Dixon J L.: Two Cases of Clostridium Welchii Infection Treated with Penicillin. *J Am Med Ass* 1944, 26 96

The development of gas gangrene in a traumatic wound depends on four factors: (1) contamination of the wound with soil or foreign bodies containing clostridia; (2) inadequate blood supply to the affected part; (3) inadequate debridement; and (4) conditions in the wound for anaerobic growth. A combination of these four factors in a given patient will almost invariably give rise to clinical gas gangrene.

Once clinical gas gangrene has fully developed the only known treatment is radical surgery, laying the affected parts wide open and many times of necessity doing a high guillotine amputation in order to save the patient's life.

Any chemical or biotic substance which will inhibit the growth of clostridia in traumatic wounds would be of inestimable value in saving limbs and lives.

The discovery of the action of penicillin and its use in experimental clostridium welchii infections held promise that this drug would be of value in such infections. As animal experiments are inconclusive in regard to human therapy it remains for the clinician to put penicillin to the final test in regard to its efficacy in the treatment of gas gangrene.

Of 2 cases of clostridium welchii infection one was treated locally with calcium penicillin and the other systemically with sodium penicillin and locally with calcium penicillin. Careful bacteriological studies showed persistence of the clostridium welchii in the case of cellulitis treated with calcium penicillin locally while the use of penicillin systemically and locally combined with guillotine amputation caused the disappearance of the beta-hemolytic streptococcus and the clostridium welchii from the spreading infection. After the oral administration of sulfadiazine beta-hemolytic streptococci could not be recovered from the blood stream. It must be emphasized that good surgery was the deciding factor in the second case, and that penicillin is of most benefit when used in conjunction with good surgical principles.

J. M. Mora, M.D.

ANESTHESIA

Hudson, F.: Four Hundred and Ten Cases of Goiter Under General Anesthesia with Pentothal. *Current Res Anesth* 944 23 211

Four hundred and ten cases of goiter were anesthetized with sodium pentothal at the Hotel Dieu in Quebec. Preoperative medication included 1½ mgm. of nembutal the night before and ¼ gr. of morphine with 1/150 gr. of atropine one hour before surgery. Two and one-half per cent solution of pentothal was given by means of the Luer Lok syringe on a tubing and the Luer Lok adapter to the needle. From five to eight minutes were allowed to put the patient to sleep meanwhile doses of 100 mgm. or 5 cc. were injected at a time. Laryngoscopic airways were kept available for emergencies. Pentothal was found to lower the metabolism, the pulse and respiration gradually becoming slower during the operation.

Four men died after the operation, one of cardiac syncope the day following, a second from bronchopneumonia on the fourth day, a third also from bronchopneumonia and a fourth from tracheal compression from a large hematoma plus cord spasm caused by the irritation. Atropine was given to avoid laryngeal spasm. Oxygen was used at the slightest sign of cyanosis and morphine doses were held down to a minimum.

The author believed that pentothal sodium was indicated in the toxic thyroid because it decreases the metabolism, is well tolerated by the patient and considerably lowers the postoperative hyperthyroid crisis.

MARY KARP, M.D.

Adams, R. C.: Pentothal-Sodium Intravenous Anesthesia in Peace and War. *J. Am. M. Ass.* 944 26 28

This month marks the end of the first decade since the clinical introduction of pentothal sodium. During each of these ten years the use of this anesthetic has increased generally throughout the country and in each year changes in our attitude toward its use, its scope, and its administration have occurred. It is

now known that it is not detoxified by the liver or kidneys and does not affect the metabolic process of the body in general. It can be used with safety when the solutions have been mixed for as long as forty-eight hours. It is usually administered in a 2.5 per cent concentration. Its margin of safety is wide. Workers with the drug vary in their opinion as to its scope of usefulness. The author discusses its administration for intra-abdominal operations and for operations in regions in which the reflexes are particularly hyperactive such as the nose, throat, larynx and anal region. He questions the advisability of using it for operations of this type. He suggests the administration of oxygen throughout, with oxygen and nitrous oxide in 50-per cent concentration.

The field of usefulness of pentothal sodium has been extended to various methods of anesthesia and it is recommended in conjunction with local infiltration block anesthesia, and local anesthesia in the very nervous patient, and to supplement local anesthesia that is wearing off or that has not been adequate. It is also recommended in a combined technique with block of the abdominal wall, or later costal block for abdominal operations. It has been used for induction in an inhalation or as either anesthesia and in combination with topical anesthetics.

Its contraindications include very young children, patients with degenerative diseases of the myocardium particularly if dyspnea is present, and operations in which the integrity of the airway cannot be assured.

The simplicity of equipment, the ease of transportation and the fire-proof qualities of this substance have caused its use in World War II to be an enviable one. It is now believed that it can be used in the shocked patient if smaller doses are administered if shock is controlled when possible before anesthesia is begun. If consideration is taken of the amount of morphine which has been given before the administration of this drug and if airways and oxygen equipment are available. An anesthetist trained in the uses of the method and the effects of the drug is important to its safe administration. Its wartime usefulness includes its administration for preliminary débridement of bomb-burned victims and persons who have sustained minor war injuries. When shock was minimal, intravenous anesthesia did not appear to aggravate the shock further. The drug is not contraindicated when patients are undergoing treatment with the sulfonamide compounds. The total dosage varies from 1,000 to 2,000 mgm. The value of the method in military surgery up to the present phase of World War II is rather gratifying.

MARY KARP, M.D.

Lettimon, W. T. and Heger, H. G., Jr.: Continuous Spinal Anesthesia: Observations on 2,000 Cases. *Ann. Surg.* 1944, 120 129.

The observations and impressions in 2,000 continuous spinal anesthetics are reported by the authors. Because of its low toxicity procaine hydro-

chloride was the agent used in all but 1 case. The advantages of the method include the ability to obtain an adequate length of time and an adequate level of anesthesia. Aspiration of the spinal fluid containing the drug promotes rapid recovery from the effects of the drug.

The technique of administration was described in detail with stress on the need for making and maintaining a good puncture. Preliminary medication consisted of the hypodermic injection of morphine sulfate (gr $\frac{1}{4}$) and scopolamine hydrobromide (gr $\frac{1}{100}$) one hour before operation. Subsequent doses of morphine were given as the need for sedation exerted itself. If the preliminary doses of ephedrine had been given with procaine for skin anesthesia it was seldom necessary to add vasomotor drugs during the course of anesthesia or operation. Among the 2,000 cases only 3 were unsatisfactory. One patient developed uncontrollable coughing during the course of a pulmonary lobectomy. Faulty technique caused failure in the 2 other cases.

The ages of the patients varied from two days to eighty-seven years. The authors found the procedure very satisfactory in children, the success depending upon the liberal use of morphine in multiple small doses. The total dosage per case averaged 310.9 mgm., the smallest dose being 20 mgm. and the largest 2,200 mgm. Five per cent solution of procaine in spinal fluid was used. Additional doses were prepared in sterile distilled water or normal saline solution. The incidence of headaches following continuous spinal anesthesia was about the same as that following the use of single-dose spinal anesthesia, and averaged about 3.1 per cent. The incidence of urinary retention was 3.3 per cent, not including the cases in which it was prolonged and indwelling catheters were used. Forty-five cases of pulmonary complications occurred. Twenty-seven of these were bronchopneumonia, 11 lobar pneumonia, 5 atelectasis, and 2 pulmonary embolism. One patient developed anesthesia of the upper lip, this disappeared in two days. No other neurological complications occurred.

The authors strongly recommend the procedure because of its adequacy, safety, and controllability.

MARY KARP, M.D.

Hilnebaugh, M. C., Jr., and Lang, W. R.: Continuous Spinal Anesthesia for Labor and Delivery. A Preliminary Report. *Ann Surg* 1944 120 143.

A malleable steel needle of the type used by Hingson and Edwards is inserted into the subarachnoid space through the first and second lumbar interspace for continuous spinal anesthesia during labor and delivery. The agent used is 1.5 per cent metycaine in Ringer's solution. The standard dose is 1 cc. or 15 mgm., repeated as necessary usually in from twenty-five to forty minutes. The height of anesthesia should be 2 or 3 cm. above the umbilicus. Any additional height may cause the danger of cessation of the uterine contractions. The dosage given was adequate to produce anesthesia but com-

Fig. 1. Sagittal section of a pregnant woman showing spinal needle in place between the first and second lumbar vertebrae. Note the needle's proximity to (1) the eleventh and twelfth thoracic nerves which carry uterine sensory fibers, and (2) the second, third, and fourth sacral nerves which carry sensory fibers from the cervix and lower birth canal.

Puncture of the dura at a higher level might result in injury to the spinal cord. Motor fibers, not shown, are involved if the anesthesia blocks the sixth or higher thoracic nerves. (Courtesy of J. B. Lippincott Co.)

plete motor paralysis did not occur. The needle was withdrawn when the patient was placed on the delivery table although the authors believe that a split mattress would make it possible to permit the needle to remain *in situ* during the entire delivery.

Complete relief of pain was obtained in 40 cases, or 80 per cent, and partial relief was obtained in 8 cases, or 16 per cent. In 2 cases the anesthesia was a complete failure. Twelve per cent of the patients required inhalation anesthesia for delivery. Dislodgment of the needles occurred in 3 cases. The labor did not appear to be lengthened. The cervix should be dilated 4 cm. and completely effaced before the method is instituted in the nullipara. A dilatation of 3 cm. is satisfactory in the multiparous woman. There was no interference with the frequency and force of the uterine contractions. Cervical dilatation seemed to be accelerated. The normal mechanism of second-stage labor was in most instances delayed. Ninety-eight per cent of the

cases had operative intervention in the second stage 56 per cent by low forceps and 12 per cent by mid forceps. Midforceps seem to be the rule in occiput posterior positions because the relaxed pelvic floor permits extension of the head with resultant arrest. The third stage proceeded normally. No case of retained placenta occurred. There was less bleeding than when other methods were used. Ninety per cent of the mothers reacted favorably to the method and were enthusiastic over the relief of pain. No alteration of the blood pressure occurred.

Twenty-two women, or 42 per cent, experienced rather severe but transient headaches which were relieved by mild analgesics. No adverse effect was found to occur upon the fetus. The indications include prematurity, heart disease, hypertensive toxemia, pulmonary disease and previous cervical, and vaginal repair. Contraindications include deformity, local infection, marked obesity, sensitivity to the drug, emotional instability, severe anemia, non-engagement of the presenting part, cephalopelvic disproportion, known fetal deformity, placenta previa, and internal podalic version.

The method is time-consuming and requires constant personal supervision. It is both unfair and dangerous to give the initial injection and place the responsibility for its continuation in the hands of an intern or nurse.

MARY KARP, M.D.

Ivy, A. C., Goetzl, F. R., and Burrill, D. V.: Morphine-Dextroamphetamine Analgesia: The Analgesic Effects of Morphine Sulfate Alone and in Combination with Dextroamphetamine in Normal Human Subjects. II. *Med. Chir.* 1944, 6, 67.

This investigation was undertaken to prove whether the administration of dextroamphetamine with morphine would influence the analgesic action of morphine in human subjects. It is known that epinephrine has analgesic properties and that the analgesic action of morphine is enhanced in the dog and the mouse by dextroamphetamine; therefore it was hoped that with the combined administration of

morphine and dextroamphetamine it would be possible to relieve pain in man without producing considerable cerebral depression.

Twenty-one healthy medical students were used as subjects. 12 of whom served twice. Sixteen received 16 mgm. of morphine sulfate and 17 received a combination of 16 mgm. of morphine sulfate and 20 mgm. of dextroamphetamine sulfate. Pain threshold, blood pressure, pulse rate, choice reaction time, and flicker fusion frequency threshold were determined in each subject shortly before the injection and at thirty minute interval and two and one-half hours after the injection.

It was clear that dextroamphetamine enhanced the analgesic effect of morphine and at the same time tended to diminish and postpone side effects which might be undesirable such as nausea, vomiting, drowsiness and general depression. In determinations of choice reaction time both groups showed improvement. In the flicker fusion tests, however, the morphine produced a definite lowering of the flicker fusion frequency threshold which indicated less efficient performance at the same time. A slight rise in blood pressure was observed at the thirtieth and sixtieth minutes in almost all of the subjects given morphine, with a drop in pressure apparent only at the ninetieth minute. The combination produced a pronounced rise in the systolic blood pressure going as high as 35 mm. of mercury in 1 patient.

From all subjective and objective evidence it is clear that in normal subjects dextroamphetamine enhances, on the average, the analgesic action and decreases the cerebral depression due to morphine. It tends to counteract and possibly delay the onset of undesired side effects. It is believed that physicians may make use of the combination of drugs experimentally in selected cases. Dextroamphetamine should not be used in doses larger than 20 mgm. because of its effect on the blood pressure in some patients. Its use should be counteracted in patients with hypertension and delirium.

MARY KARP, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

McCort, J. J.: Roentgen Features of Chronic Tuberculous Peritonitis. *Arch Surg.*, 1944, 49, 91

Tuberculous peritonitis may be divided into two main types: acute and chronic. There are two varieties of the acute type: the military and the localized. In a small percentage of the localized type of peritonitis the tubercles break down and invade the greater part of the peritoneum and thus give rise to chronic peritonitis. Acute localized peritonitis is usually found in children. No roentgenological studies of this form have been reported.

Chronic tuberculous peritonitis is considered by pathologists to be a secondary infection in all cases. It may develop by one of three routes: (1) perforation, (2) lymphatic channels, and (3) blood stream. At the Massachusetts General Hospital, Boston, in the past five years 17 cases of tuberculous peritonitis were found among 182,390 admissions. In 3 the diagnosis was made on clinical grounds alone and in 14 on the basis of laboratory findings.

In the wet form of tuberculous peritonitis the plain roentgenogram taken in an early stage of the disease usually shows ascites with a low grade ileus. A diffuse haziness of the abdomen is seen with obliteration of the outline of the psoas muscles and the subperitoneal fat. The small intestine, which is usually filled with gas, appears to be floating freely in the abdomen. The diaphragm is elevated. In the dry form of tuberculous peritonitis the plain roentgenogram shows evidence of ileus alone. The small intestine is drawn up high in the abdomen. Examination of the colon by the barium-enema method is more informative. In tuberculous peritonitis the intestinal wall is rigid with areas of narrowing and areas of dilatation, and the bowel is freely movable in the peritoneal cavity. In roentgenograms taken after evacuation of the barium-sulfate enema, there is normally a descent of the entire transverse colon, but in tuberculous peritonitis there is little or no change in the position. Adhesive bands may be found retracting the intestinal wall.

Of greatest value is the study of the small bowel. The first abnormality noted is the rapid passage of barium, only about six minutes being required for transit. Rigidity and fixation of the loops of the small intestine are marked and there is little change in their position. The small intestine is shorter and occupies a smaller space than normal. In the intervening space the barium-filled loops of small bowel may be slightly widened and irregular because of the presence of fluid and fibrin between the peritoneal surfaces. The arrangement of the loops of the small bowel is irregular and bizarre. Abnormal segmentation of the barium-filled small bowel indicating a disturbance of the intestinal motility may also be distinguished.

The differential diagnosis is discussed. Six cases of tuberculous peritonitis are presented in 3 of which the preoperative diagnosis was suggested by the roentgen appearance of the large and small bowel.

HAROLD C. OCHSNER, M.D.

Ochsner, H. C.: Cholecystography with Beta (4-Hydroxy 3,5-Di Iodophenyl) Alpha Phenyl Propionic Acid. *Gastroenterology* 1944, 3, 23

The author gives a brief historical review of cholecystography beginning with February 1924, when Graham and Cole announced the revolutionary discovery of the use of calcium tetrabromphenolphthalein for intravenous cholecystography. The various contributions that followed have given rise to a voluminous literature. The drug that proved to possess the widest margin of safety was sodium tetraiodophenolphthalein which could be administered by the intravenous, or preferably the oral, route. This drug has been used almost exclusively since 1925.

In 1940 Dohrn and Diedrich reported their experimental work with another substance, the beta (4-hydroxy 3,5-di iodophenyl) alpha phenyl propionic acid which they called "biliselectan" but which in this country is known under the trade name of prodxal (Schering). Several articles appeared since then dealing with the clinical aspect of its use. All writers appear to have been impressed by the reliability of this new contrast medium and by the low incidence of toxic reactions.

The author himself has previously reported his favorable experience with 300 cases and now he extends his observations to 600 cases.

Since prodxal is largely excreted in the urine its only contraindication is serious renal disease, especially when there is retention of metabolites.

A single dose of 3 gm. is given taken in the form of 6 tablets each containing 0.5 gm. of the radiopaque substance. The author believes that the double dose in heavier patients is unnecessary. The procedure otherwise remains the same as with previous cholecystographic media.

In 56 per cent of the examined 600 patients, there was no reaction. In 5 per cent the reaction was mild and in 39 per cent it was somewhat more pronounced. Nausea occurred in 24.6 per cent (in a very few cases there was vomiting), diarrhea in 14 per cent, abdominal pain in 9 per cent and pain on urination in 5 per cent. In several cases there was an association of two or more symptoms.

The visualization of the gall bladder has been definitely superior to that obtained previously by the author when using the divided double dose of sodium tetraiodophenolphthalein. Confusing shadows in the intestine which were sometimes troublesome with the old dye were absent because of the predominant excretion of this new medium through the urinary tract.

A statistical compilation revealed that the visualization of the gall bladder was excellent or good in 67 per cent of the total cases, with presence of stones in 7 per cent and poor in 13.5 per cent, with stones in 47 per cent. In 18.5 per cent there was no visualization, with stones in 34 per cent of this group.

Slightly more than 10 per cent of the patients examined were operated upon. Surgical confirmation was satisfactory in all but 4 (6.3 per cent of the operative group). In these the gall bladder had been functioning normally, but evidence of cholecystitis was found by the pathologist.

The conclusion is reached that (1) proflax is a reliable cholecystographic medium which produces gall bladder shadows of excellent clarity, and (2) its administration is associated with fewer and less intense reactions than has occurred with sodium tetrastannophthalate. T. L. COTTELL, M.D.

McGee, J. J., Davidson, C. N., and Walton, H. J.: Determination of the Placental Site in Bleeding during the Last Trimester of Pregnancy. *Am J Roentg* 1944 42: 1.

Maternal mortality in placenta previa reported the literature from 1 to 10 per cent. Therefore it is readily understood why bleeding in the last trimester of pregnancy is a source of worry to the obstetrician.

An excellent historical review is given of placental visualization by means of roentgen rays. One of the first feasible clinical methods was demonstrated by Le Deum, and Lamer in 1934. They found that a diagnosis of placenta previa could be made on the finding of a soft tissue mass between the fetal head and the maternal bladder after the bladder had been filled with opaque media. The normal average distance between the fetal head and bladder was 1 cm. One drawback to the Ule *et al* method was that a definite diagnosis could not be made when the placenta was implanted on the posterior wall of the uterus with only a margin or a few centimeters overhanging the os.

In the same year (1934) that Ule *et al* made their studies, Snow and Powell demonstrated that the placenta could be visualized in a lateral view of the abdomen. No special apparatus or technical studies were necessary. All that is required is a soft tissue technique (300 ma.-sec. 36 in. distance and kilovolt to vary with the patient's thickness). Instead of the usual lateral abdominal technique, a bright light is used to visualize the placenta and the soft tissue of the abdomen. In addition, experience in the interpretation of such films is required.

A restudy of 132 cases at the University of Maryland Hospital from November 1938 to February 1943 was done. A correct diagnosis was made in 87.8 per cent. A correct negative diagnosis was made in 97 per cent of this group. A negative diagnosis is just as important as a positive one because the obstetrician can then allow the patient to go to term without worry of a sudden fatal hemorrhage. Marginal placenta previa was diagnosed correctly in 60 per

cent of the cases. In addition to diagnosing placenta previa, the obstetrician may be able to locate the position of the placenta, in the event that a cesarean section is indicated.

The technique used by the authors is described. An anteroposterior and lateral abdominal film is taken with 300 ma.-sec. 36 in. distance, Potter-Bucky diaphragm and from 65 to 75 kilovolts, the variation depending upon the thickness of the abdomen. The average thickness of the placenta is 6 cm.

The placenta was visualized in the majority of the cases by using the soft tissue technique. In doubtful cases a pneumocystogram was done. Air is preferred to opaque media for insertion into the bladder because it is cheaper, nonirritating and offers more contrast.

In placenta previa or low implantation of the placenta the vertical pelvic measurement is 2 cm., whereas the normal is 1.2 cm. An additional roentgen sign is the displacement of the bladder to either side when the placenta is on the lateral uterine wall.

The authors point out that roentgen examination for placenta previa does not eliminate the value and necessity of doing a sterile pelvic examination. Both examinations are complementary.

MATTHEW D. SUGGS, M.D.

Auerbach, O. and Stemmerman, M. G.: The Roentgen Interpretation of the Pathology in Pott Disease. *Am J Roentg* 1944 53: 57.

The classical roentgen signs of Pott disease are the narrowing of the intervertebral disc and the collapse of the vertebral bodies with or without the shadow of a cold abscess. During the past ten years the authors repeatedly found that these signs represent only part of the picture and that often the tuberculous involvement of the spine is considerably more extensive than could be suspected from the roentgen examination alone. The purpose of the present article is to try to co-ordinate these discrepancies.

The study is based on a material of 135 roentgen examinations performed at Sea View Hospital, Staten Island, New York, the presence of Pott disease being observed in 132 cases (9 per cent). Of the 132 patients, 100 had had roentgen examinations of the spine usually less than six months before death, so that a comparison of the pathological and roentgen findings could easily be accomplished.

The age distribution ranged between two and sixty-seven years, with 35 per cent of the patients being in the second and third decades of life. Fifty-five per cent were negroes, 43 per cent whites, and 2 per cent Chinese. Since at this institution the ratio of negroes to whites in the general autopsy material represented as 4 to 7, this preponderance of negroes appeared the more striking.

Of the 132 cases, 49 (37 per cent) were under 15 years of age, although the presence of the lesion was suspected in 18. There was an active chronic pulmonary process in only 35 (26 per cent) of the cases, a urogenital tuberculosis in 38 (29 per cent),

and both chronic and urogenital tuberculosis in 11 cases.

The number of vertebrae involved also varied. In only 6 of the 132 cases was there involvement of a single vertebra. In 39 (30 per cent) two adjacent vertebrae were affected, in 24 (18 per cent) three adjacent vertebrae, and in 63 (48 per cent) more than three. In the last group the disease was usually but not always found in contiguous vertebrae. The most severe case showed a contiguous extension from the fifth cervical vertebra to the coccyx. The lower dorsal and lumbar vertebrae were most frequently involved followed in order of incidence by the sacral lower cervical and upper cervical vertebrae.

From the pathological standpoint it is important that the affected bone may assume two forms: a productive (sclerotic) and an exudative (caseous destructive) form. If multiple vertebrae are involved the two forms may be found to occur in combination.

From the roentgen standpoint it is the destructive type of Pott's disease that acquires the well known classical appearance. When the vertebral body is collapsed and the intervertebral disc is destroyed the diagnosis is simple when the caseous process is limited to the central portion of the vertebra or its small parts, the diagnosis may be more difficult but the general clinical appearance of the patient and the demonstration of sinuses and fistulas etc. in the end will aid to clarify the situation. However in the essentially productive type of Pott's disease experience shows that a roentgen diagnosis is well-nigh impossible. In the authors series the destructive form of Pott's disease remained roentgenologically undiagnosed in only 10 per cent of the cases but the productive form was not recognized in a single instance, although at autopsy it was found in 25 per cent of all the examined cases.

In order to discover some signs that could be used roentgenologically to diagnose the productive type of Pott's disease, the authors made numerous roentgenograms of hemisections of spines taken at autopsy. They found under these roentgenologically ideal conditions, one change which occurred rather constantly. This change appeared in the form of "sclerosis," or an area of increased density corresponding exactly to the diseased areas noted grossly although pathologically these areas were nothing more than marrow spaces filled with granulation tissue and caseous material. In reviewing the roentgenograms taken before death with this change in mind, the authors were still unable to detect any thing of diagnostic significance. It is possible however that with a more specialized technique, and especially with serial roentgenograms, one may obtain better results. The demonstration of certain complications of Pott's disease may also assume, in this respect added importance. Such complications are the cold abscess which was noted in 96 per cent of the authors' cases at autopsy and the tuberculosis of the ribs which occurred in 18 per cent of the cases.

T. LEUCUTIA, M.D.

Pendergrass, E. P., Hodes, P. J., and Griffith, J. Q.: Effect of Roentgen Rays on the Minute Vessels of the Skin in Man. *Am. J. Roentg.* 1944 52: 123.

A preliminary study is reported on the immediate effect of roentgen rays on the minute vessels of the skin in man.

For this experimental study there were 84 white ambulatory patients. The extensor skin surface of each patient's midforearm was studied. Two areas of about 2 sq. cm., 4 inches apart, were marked off and studied. Precautions were taken to protect the forearm even against minor injury. A capillary count was taken in the morning after breakfast. One forearm was subjected to irradiation and the other was used as a control. Irradiation was given about one hour after the normal capillary count. A second and third capillary count was made six and twenty-four hours, respectively after irradiation. A final count was then made after a drop of histamine 1/1000 was injected near the area being studied.

Patients were divided into four groups according to the type of irradiation used. Technical factors used in the first three groups were almost alike: namely 200 kv., an oil immersed tube with equivalent inherent filtration of 0.25 mm. of copper 0.5 mm. of copper plus 2 mm. of aluminum filtration 20 ma., except in the third group in which 5 ma. were used. In the first group the target skin distance was 15 cm. with a 444 roentgen per minute output. Short tube skin distance was selected for high intensity. In the second group the skin target distance was 50 cm. with a 52 roentgen per minute output. In the third group at 50 cm. skin target distance and with 5 ma. the output was 10 roentgens per minute. For the fourth group a Chaoul contact therapy unit was used operating with 50 kv., 4 ma., 2 mm. of nickel inherent filtration and skin target distance of 3 cm. the output was 300 roentgens per minute.

The patients in all four groups were given irradiation amounting to from 300 to 333 roentgens per 2-sq.-cm. area at one sitting.

In Group I in which a short skin target distance was used (333 roentgens in three-quarters minute) the skin capillaries were dilated in six hours and after twenty-four hours most of them had disappeared. In Group II in which the skin target distance was 50 cm. (301 roentgens in seven and two-tenths minutes) the capillary dilatation was observed after six hours and to a lesser extent after twenty-four hours. In Group III in which the milliamperage was changed from 20 to 5 (308 roentgens in thirty and eight tenths minutes) no change was observed in the skin capillaries after six and twenty-four hours. In Group IV with a Chaoul contact therapy unit (300 roentgens in one minute) a moderate capillary effect was noted after six hours which became more marked after twenty-four hours.

Attention is directed to the differences in response of skin capillaries to irradiation. These differences are related to the method of irradiation.

MAURICE D. SACHS, M.D.

Mattick, W. L.: Some Experiences in the Treatment of Bronchial Cancer. *Am J Surg* 1944 52: 4

One of the greatest difficulties in treating bronchial cancer is our inability to make a sufficiently early diagnosis. Another is the tendency of every type of bronchogenic cancer to produce in a distant lymphatic permeation toward the hilar lymph nodes and a metastasizing hematogenous dissemination to distant parts of the body.

A review of 14 cases observed at the State Institute for the Study of Malignant Disease in Buffalo showed that approximately from 30 to 40 per cent of the patient had demonstrable metastases to the hilar nodes, egg nest lung bones, superficial nodes or liver when first seen. Operation then were poor risk for any therapy. There was left a group of between 10 and 15 per cent to whom aspiratory thoracotomy could be applied but in these too for one reason or another surgery was performed rarely. The most of the patient either because of necessity or desire on their part were referred for radiation therapy.

The latest best results have been obtained from 300-ky therapy although more recently 400-ky and even 1,000-ky therapy is being applied. The bronchial cancer is cross fired so as to build up a total dose of 2,000 roentgens with properly directed and angulated portals directed ventrally, anterior and two posteriorly. A supplementary course of similar irradiation after one or two months through previously nonirradiated portals probably three or four may be given.

In 4 selected cases gold radiation seed introduced through a bronchoscope may be implanted directly to the accessible cancer.

In 4 cases all proved histopathologically a long result ranging from three to five years were obtained. These cases are described in detail and illustrated with roentgenogram as well as with photographs of the histological section.

The conclusion is reached that such results while not entirely unusual, are better than indicated in many reports of the surgical radiation or combined treatment of this condition cited in the recent literature. T. LARSEN, M.D.

MISCELLANEOUS

Rntschler H. D. and Settle J. W. Jr. Treatment of Impaired Hearing by Radiation of Excessive Lymphoid Tissue in the Nasopharynx. *Penns Surg* 1944 72: 944-47-945

The literature indicates that there is a recurrence of the adenoid tissue in 75 per cent of the children having tonsillectomies and adenectomies before puberty. In many instances the orifices of the eustachian tubes are blocked by lymphoid tissue and hearing is impaired. Hearing impairment begins with the high tones and gradually involves the entire speech range. The earlier the treatment started for the defective hearing the better the results that can be obtained.

The authors believe that such conditions can be diagnosed early by routine school examinations in conjunction with the physician. In those instances where there is a massive recurrence of lymphoid tissue especially in the lateral walls of the pharynx, eustachian tube orifices, surgery is not particularly desirable. Lymphoid tissue irradiation by radium or radon or external irradiation may be used. Radium or radon is preferable inasmuch as the element can be placed next to the lesion which will minimize the amount of radiation given to normal tissue. Radium has the advantage over radon in that the tubes can be made long enough to fit the lesion, and the treatment time is shorter because a greater quantity of radon can be placed in each tube. A dose of 2 gm. in minutes to either side of the nasopharynx is sufficient. This may be repeated after a month, if necessary.

Internal irradiation has the advantage of being extracted and it is difficult to hold a child's head still. However, the mother properly protected, can hold the child's head. The irradiation that normal tissue receives is negligible. Treatment with 200-ky 1 mm. of copper plus 1 mm. of aluminum filters at 50 cm. focal skin distance and 100 roentgens to two lateral 6 by 8 cm. fields for four consecutive days usually sufficient.

Thirty-six patients received radiation therapy for impaired hearing associated with nasopharyngeal lymphoid hyperplasia. Sixteen patients were between the ages of seven and nineteen years and their hearing restored to normal and 7 had some improvement in their hearing. One patient, the history of mastoidectomy ten years previously and progressive deafness failed to respond to the treatment. The case histories are presented.

M. TUCKER D. SUGGS, M.D.

Simchowitz H. C.: German Radiotherapy in 1942 and 1943. *Br J J Radiol* 1944 17: 216.

The author, after a lapse of 10 years, has just received Volumes 2 and 73 (1942 and 1943) of *Strahlentherapie*. A reading of the published articles gives the impression that while British radiotherapy was advancing rapidly, German radiotherapy remained stagnant. Most of the articles are by German and Austrian authors with a sprinkling of Hungarians and Swiss. It is significant that there is no publication at all from the formerly leading German radiotherapy centers in Frankfurt (Hofmeister) or Hamburg (Hilthsen) and that Hoffelder has been invited by the German government to go as radiotherapist to Posen in occupied Poland, an honor which he apparently accepted.

Briefly some of the more important articles are as follows:

J. HENKEL (Heidelberg). Report of the Cancer Institute of the University of Heidelberg (on 5,000 cancer cases treated by radiotherapy alone). The five year cures which Simchowitz compares with those of the Christ Hospital and Holt Radium Institute of Manchester are as follows:

Heidelberg	Per cent	Manchester	Per cent
Total cures (of 5,000 cases)	8	Total cures (of 1,000 cases)	40
Breast (operable)	98	Skin	85
Skin	33	Lip	63
Lip	16	Floor of mouth	34
Floor of mouth	25	Cheek	29
Cheek	5	Tongue, anterior $\frac{1}{2}$	32
Tongue	7	Tongue, posterior $\frac{1}{4}$	1

K. G. ZIMMER (Berlin) Protective Material in Radium Work. Uranium, instead of lead or tungsten alloy is recommended.

A. KREBS (Frankfurt) The Total Radium Contents of the Human Body. The crematorium ashes of a great number of normal individuals (not of persons dying of radium poisoning) revealed an average radioactivity corresponding to $1.0-1.5 \times 10^{-4}$ gm. of radium element.

EWALD (Heidelberg) Radiotherapy in the Army. Irradiation of the spleen (100 roentgens) is recommended to promote coagulation of the blood pre or postoperatively in hemorrhagic diathesis.

H. BRAUNBERGENS (Freiburg) X-ray Therapy in Salivary Fistula. Since salivary fistula is not an infrequent war injury particularly in gunshot wounds temporary suppression of the parotid secretion is recommended by means of irradiation, which in most cases will produce a quick healing of the fistula. A dose of 300 roentgens given daily for from five to seven days is recommended. No permanent damage to the parotid gland has been observed up to the time of the report.

Other articles deal with the treatment of hemangioma especially in babies with Chaoul therapy or interstitial radium therapy also the treatment of spondylitis humeroscapular periarthritis Schueller Christian's disease of the skull, prostatic lesions carcinoma of the esophagus, carcinoma of the vulva and carcinoma of the larynx. Schink (Zurich) gives a very good review of recent advances in experimental cancer research and Zuppinger (Zurich) discusses the implications of the second course of protracted fractionated roentgen-ray therapy.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Thomas H. B., and Lelphart, C. D. Septicemia and Purpura with Adrenal Hemorrhage in the Adult (Waterhouse-Friderichsen Syndrome); the Role of the Adrenal Gland in the Production of the Syndrome. *J. Am. Med. Ass.* 944 5 884.

The syndrome of bleeding into the skin and other organs including the adrenal glands, in the presence of a severe septicemia is becoming more frequently recognized by clinicians both here and abroad. Of 150 cases that have been reported previously, the vast majority occurred in infants and young children.

After some years of investigation by modern bacterial methods, it seems definitely established that the most frequently invading organism is the meningococcus. It is the growing opinion that the neisseria meningitidis will be indicted as the sole etiological agent. In the authors' review of 31 cases in adults, including 2 of their own, the meningococcus has been cultured or reasonably well identified on sections in 6 reports. The meningococcus is not universally accepted as the sole etiological factor. Lindsay and his associates reported 7 cases in children in which the heart's blood culture showed 4 to be positive to neisseria meningitidis, 2 to haemophilus influenzae and 1 to neisseria flava II. In case 2 of Sacks, the postmortem culture revealed a pneumococcus of type I. The occasional finding of the pneumococcus is of great interest because of its characteristic, like that of the meningococcus which produces purpuric skin lesions.

The concept that the hemorrhagic destructive lesion of the adrenal glands is the cause of the dramatic death of the victim has been accepted for a number of years. It is the opinion of the authors that death occurs from an overwhelming septicemia with a superinduced profound state of shock. The reason that massive adrenal hemorrhage excites interest is that it has long been known that loss of the adrenocortical hormone produces fatal disorders of systemic functions that are identical in most features with those of surgical or traumatic shock.

In the reported cases of recovery from the Waterhouse-Friderichsen syndrome the clinical features are identical with those that are fatal. It is difficult to visualize even mild bilateral hemorrhagic lesions of the cortex which could produce such profound disturbances in the individual and still allow recovery of complete function. The sequence of events in the production of the Waterhouse-Friderichsen syndrome is undoubtedly initiated by a bacterial invasion of the blood stream. That most cases of meningococcal meningitis show a stage of dissemination in the blood stream after a period of local infection in the upper respiratory tract is generally accepted. The cause of the wide hemorrhagic phenomena of

the skin, adrenal glands, and many other tissues has been thought to be the direct action of the bacteria or their toxins on the walls of the capillaries. Removal of the adrenal medulla will produce no definite change in the physiology of the animal, and it has been noted by many investigators that the surgical removal of both adrenal cortices will not produce the symptoms of insufficiency for at least several days. The clinical evidence for the concept that adrenal hemorrhage plays little or no part in the rapid death of the patient is furnished by Williams who states that adrenal hemorrhage is but an incident in an explosive disease that overwhelms all bodily resistance. The status of the thymolymphatic system plays no part in the adult cases. As the adult cases are similar to the juvenile, it may be assumed that it is almost never a factor.

The clinical picture is almost the same in adults as in children. The most common symptoms are malaise followed by chills, fever, sweating, and manifest weakness. General aching with abdominal pain or cramps and vomiting occur later. Cyanosis and the purpura are the symptoms which cause alarm. Laboratory examinations are frequently meager and inconclusive because of the short duration of the disease. Usually there is a rather accentuated leucocytosis. Chemical examination of the blood reveals the same findings that are generally found in shock. Rapid diagnosis can be made in smears of the purpuric areas.

The outstanding pathological feature is bilateral adrenal hemorrhage. Other postmortem findings are hemorrhage into the serosal cavities and intestinal tract, pulmonary engorgement and injection of the vessels of the brain and enlargement of the thymus, lymph nodes, Peyer's patches, and spleen. Two cases are presented in detail by the authors.

Therapy falls into two categories, specific and supportive. Chemotherapy with sulfadiazine in the form of the sodium salt should be given at once. About 0.05 gm. per pound of body weight is the initial dose to be given intravenously; the total daily requirement thereafter being approximately the same. The sulfadiazine level should be kept at 15 mgm. per 100 cc. Sulfathiazole is the drug of second choice followed by sulfapyridine and sulfanilamide. Polyvalent antimeningococcus serum should be started along with chemotherapy in doses of from 50 to 150 cc. intravenously, repeated every six to twelve hours for three doses, and daily thereafter if necessary. The intravenous use of meningococcus anti-toxin in 100,000 units may be substituted for the serum.

Supportive measures include the use of fluids and sodium chloride to combat dehydration, large and adequate doses of plasma to combat shock, oxygen, and the use of adrenocortical extract to combat the capillary permeability. Adrenocortical extract is

given twice daily in 10 cc. doses or the equivalent dose of the synthetic cortical derivative desoxycorticosterone. One dose of epinephrine may be given. The authors believe that early and less severe cases should be given all that modern therapeutics has to offer.

HERBERT F. THURSTON, M.D.

DUCTLESS GLANDS

Voitz, C. P., and Smull, K.: Hyperparathyroidism, with Failure to Recalcify after Removal of Parathyroid Adenoma. *Ann Int M* 1944 21 320.

A case is presented in which five years after the removal of an adenoma for the relief of hyperparathyroidism recalcification had failed to occur even though after the operation there was no evidence of recurrent hyperparathyroidism. Failure of bone recalcification despite the prolonged normal serum calcium level is attributed to the lack of increased osteoblastic activity which is suggested by normal preoperative and postoperative serum phosphatase levels.

WALTER H. NADLER, M.D.

Reveno, W. S.: Thyrotoxicosis Treated with Thiouracil. *J Am M* 1944 126 133.

The effect of thiouracil in the treatment of 9 ambulatory patients with toxic thyroid adenomas was studied for a period of eight months. In this series reactions in the form of urticaria, skin rashes, agranulocytosis, anemia, edema or jaundice were not observed. The time period before improvement became manifest from thiouracil therapy varied from two to fourteen weeks. Clinically 6 of the 9 patients showed significant improvement in thyrocardiac symptoms and a fall in the basal metabolic rate. Three patients failed to respond to thiouracil, one of these had received prolonged iodine medication. Histologically areas of hemorrhage and necrosis were found in the substance of the gland as a result of the thiouracil medication. It also appeared that iodine medication inhibited thiouracil hyperplasia of the thyroid.

BENJAMIN G. P. SHAPIROFF, M.D.

Moore, F. D., Sweeney D. N., Jr., Cope, O., Rawson, R. W., and Means, J. H.: The Use of Thiouracil in the Preparation of Patients with Hyperthyroidism for Thyroidectomy. *Ann Surg* 1944 120 152.

The ideal preparative drug for thyroidectomy would be one which so modified the underlying metabolic abnormality as to bring the patient to the surgeon with no evidence of thyrotoxicosis, this would allow him to remove the gland and produce permanent relief without subjecting the patient to the hazards of surgery while thyrotoxic. It was the purpose of the authors to ascertain to what degree thiouracil was given to 53 thyrotoxic patients as a preparation for thyroidectomy. Of these 34 have come to operation and have been followed up long enough to form a basis for study. Of these 34, 26 received thiouracil as the only preparative drug. The daily

dose was 0.6 gm usually administered as 0.2 gm in three doses. As a control series 35 thyroidectomies for thyrotoxicosis performed in the same hospital in the years 1941 and 1942 were selected the patients had been treated with iodine.

From their careful and well controlled work the authors found thiouracil superior to iodine because regardless of the degree of elevation of the metabolic rate prior to therapy it will bring the patient's basal metabolic rate to normal.

The histological change accompanying this lowering of the basal metabolic rate is an intensification of the hyperplasia seen in the thyrotoxicosis. Thiouracil produces a hyperplastic but nonfunctioning goiter. An occasional disadvantage of the use of thiouracil in preparing patients for surgery lies in the fact that this hyperplasia is accompanied by an increased vascularity and friability which makes the gland more difficult to handle and renders hemostasis arduous. The increased vascularity is especially troublesome if the patient has had a previous thyroidectomy.

Preliminary or concomitant iodine administration delays the thiouracil response. It is possible that iodine therapy subsequent to thiouracil treatment may play a useful role in reducing hyperplasia and vascularity.

Toxicity not unlike that of the sulfonamides may be expected to occur when patients are treated with thiouracil.

Thiouracil while an improvement over iodine as a means of preparing patients for surgery, is not yet the ideal drug for this purpose because it increases the histological abnormality of the disease. Also it affects only the production of hormone and not the underlying etiology of hyperthyroidism. Surgery may be rendered difficult because of the increased vascularity of the gland and lastly thiouracil is toxic to some of the patients.

EARL O. LATIMER, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Warren, S., and Ehrenreich, T.: Multiple Primary Malignant Tumors and Susceptibility to Cancer. *Cancer Res.*, 1944 4 554.

In a series of 2,829 cancer autopsies 194 cases of multiple malignant neoplasms were encountered an incidence of 6.8 per cent. Together with the series previously reported there were 3,907 autopsies with an incidence of 6.0 per cent multiple cancers.

In the group of 194 patients with multiple malignant tumors there were 131 males and 63 females.

The average age of the male group was sixty-five and two-tenths years of the female group fifty-six and nine tenths years and of the entire group sixty-two and five tenths years.

The average duration from onset of the first tumor until death was two and seven tenths years.

The average interval between successive tumors when it could be determined was three and one tenth years.

Cases of multiple malignant growths occur more frequently than the expected incidence based on chance alone.

This greater frequency calculated as elevenfold may be attributed to susceptibility or predisposition to cancer in some persons or groups of persons.

JOHN J. MALONEY, M.D.

Haddow, A., Watkinson, J., Paterson, E., and Koller, P. C.: The Influence of Synthetic Estrogens on Advanced Malignant Disease. *Brit J J* 944 : 393

In the investigation of the mechanism of action of tumor producing compounds it was found that many carcinogenic hydrocarbons possess the property of retarding the growth of tissues, both normal and malignant. A few of the carcinogenic hydrocarbons possess slight estrogenic activity while in certain cases these two classes show interesting relationships on chemical grounds. Contrariwise, certain of the estrogens exert carcinogenic action in animals. The estrogens thus provide an example of compounds possessing growth-retarding properties and properties capable of producing a physiological stimulation of growth or the formation of tumors under certain circumstances.

The authors report the findings in 40 cases of carcinoma of the breast and in 33 cases of malignant disease in other organs treated with the synthetic estrogens triphenylchloroethylene triphenylmethylethylene or stilbestrol.

Of 23 cases of late malignant disease of the breast treated with triphenylchloroethylene 10 showed a significant although temporary retardation or even partial regression of the growth of the tumor. No evidence was obtained to suggest that the drug will prevent the development of metastases. The initial effect of treatment in these cases passes off comparatively rapidly.

Of 30 cases of advanced malignant disease other than cancer of the breast (including carcinomas of the skin, maxillary antrum, urinary bladder, ovary, rectum and testis, with reticuloendothelial growths and leucemia) similarly treated with triphenylchloroethylene, only 2 (carcinoma of the bladder and carcinoma of the prostate) showed undoubted partial regression of the tumor.

Of 4 cases of mammary cancer and 3 cases of Hodgkin's disease treated with triphenylmethylethylene (usually by intramuscular injection) only 1 (spheroidal-cell carcinoma of the breast) showed even a temporarily favorable response.

Of 14 cases of carcinoma of the breast treated with stilbestrol (by intramuscular injection or by mouth over a period of several months), 5 showed alterations in the growth and behavior of the tumor similar in nature to those produced by triphenylchloroethylene.

The cases reported afford no contribution to effective therapy but the results are of considerable fundamental interest, and provide an incentive to further investigation.

JOSEPH K. NARAT, M.D.

Gill, A. J.: Local Eosinophilia in Malignant Neoplasms. *J Lab Clin M* 944, 89-90

Eosinophile infiltration has been observed in many instances in the stromal tissues of a variety of neoplasms. It is most marked and is seen most frequently in cases of epidermoid carcinoma of the cervix. The neoplasm itself is not remarkable in appearance and there is no very impressive histological picture which distinguishes such tumors with the exception of the marked local eosinophilia which may be observed.

The inflammatory reaction in the stroma of carcinoma of the cervix is somewhat variable, although in most instances there is a rather marked infiltration of lymphocytes, plasma cells, and moderate number of large mononuclear cells. Polymorphonuclear eosinophiles occur with somewhat less frequency. Eosinophiles are present in the vast majority of cases, but usually are few in number and widely scattered. They are probably not much more numerous than might be expected in many chronic inflammatory processes. In a small percentage of cases these cells appear to be absent. However in another small group of carcinomas of the cervix there is an infiltration of eosinophiles which is definitely greater than that seen in the great majority and which in a few cases exceeds the number of all other inflammatory cells present.

The characteristic lesion of the type under consideration reveals a moderately undifferentiated epidermoid carcinoma, in the stroma of which there is a dense infiltration of typical eosinophiles. Occasionally the tumor stroma is entirely obscured by the large number of these cells which lie closely packed together.

The causes of the marked local infiltration of eosinophiles in some cases of malignant neoplasms are obscure. None of the usual explanations for eosinophilia seem entirely adequate. It is possible that special conditions of necrosis with liberation of protein-degeneration products, or unusual bacterial infection of ulcerated lesions, or perhaps a strong allergic susceptibility of an individual to either protein-degeneration products or bacteria may account for this phenomenon. It seems much more reasonable to assume that the reaction is due to some change probably degenerative in the tumor or in the tissue of the host, or in both. This may not be different from an allergic reaction of the host to a protein antigen.

What is thought to be a significant degree of local eosinophilia was observed in 77 per cent of a series of 309 cases of epidermoid carcinoma of the cervix. There is some reason to believe that the abundance of eosinophiles in the stroma of malignant tumors is of good prognostic import (other factors being equal), and probably represents a better than usual resistance to the advance of the neoplasm. It is hoped that future long term observations with follow-ups will confirm the value of this phenomenon as a favorable indication for the prognosis.

BENJAMIN GOLDMAN, M.D.

EXPERIMENTAL SURGERY

Price, P. B. Metcalf, W. Longmire, W. P. Hannon, C. R., and Rizzoli, H. V.: Experimental Shock. Effects of Acute Plasmapheresis in Healthy Dogs. *Bull. Johns Hopkins Hosp.* 1944 75 14

Whether or not shock produced by hemorrhage alone is similar to shock produced mainly by local fluid or plasma loss is a controversial question. In two series of experiments reported plasma and whole blood were removed under almost identical conditions; hence comparison seems valid.

After blood loss there is usually slight hemodilution after plasma loss there is a high degree of hemoconcentration. In both conditions, systemic anoxia finally occurs. In hemorrhage the mean arterial blood pressure is a fairly reliable index of shock, but the hematocrit is unreliable. In acute plasmapheresis the hematocrit is often the most dependable criterion. Vasoconstriction seems to be a less prominent factor in plasmapheresis than it is in hemorrhage. Cardiac output is much the same in plasmapheresis as in hemorrhage even though the blood is much more viscous. Hemorrhages into the adrenal glands are not so pronounced after plasmapheresis as they are after massive hemorrhage.

Uncomplicated posthemorrhagic death follows a fairly uniform pattern: the blood pressure declines slowly, breaks sharply, and death occurs from ten to twenty minutes later during the last two or three minutes the heart rate changes from rapid to slow and the respirations which were deep and fast suddenly falter before the heart stops beating. The course of acute plasmapheresis may be similar but in many cases, especially when the hematocrit is high, the heart stops suddenly the blood pressure, which may have been comfortably high, plummets to zero and the animal, after a few spasmodic respiratory efforts dies. Finally the postmortem appearance of the organs and tissues is somewhat different in the two conditions although in neither case is there much evidence of the "pooling" of blood extensive petechial hemorrhages or systematic capillary permeability.

Primary effects of acute plasma loss. These are hemodynamic: reduced blood volume, increased blood viscosity, decreased blood flow through the heart and body tissues, and low arterial and venous pressures. Fundamentally, these are simple physical effects, modified by physiological adaptations.

Secondary effects of acute plasma loss. If not compensated for, the vital functions of the blood are necessarily disturbed by the reduction of its volume by slowing of its rate of flow and by incomplete pulmonary oxygenation. A function of blood is to supply adequate amounts of oxygen to the tissues continuously particularly to vital centers and organs. Severe anoxemia quickly leads to dysfunction and death. Other vital processes such as the elimination of carbon dioxide, regulation of the body temperature, the water and electrolytic balances, nutrition and hormonal activities are likewise dependent upon

an efficient blood circulation. Consequently depression of the circulation by plasmapheresis might be expected to produce a variety of functional and organic abnormalities. Actually few were found in these acute experiments. The reason perhaps is that oxygenation is the function of the blood most promptly and seriously deranged by severe plasma loss and animals succumb from anoxia before other pathological changes have had time to become manifest. Furthermore the paucity of abnormal anatomical changes gross or microscopic, suggests that the deleterious effects of anoxia are largely functional.

The sudden failure of the circulation in late stages of plasmapheresis shock is not easy to explain satisfactorily. No abrupt vasodilation change of heart action, alteration in volume or concentration of blood, or abnormal capillary permeability was detected at the time of the break in the blood pressure. Some of the animals with high hematocrit and well sustained blood pressure collapsed rapidly and died without warning as though the heart exhausted by attempts to force viscous blood through the vascular system suddenly gave out entirely. There was no evidence of acute dilation of the heart.

The secondary pathological effects of acute plasmapheresis though vaguely manifested are of the utmost importance. They may be fatal. Anoxia resulting from an impaired circulation tends reciprocally to depress the circulation further and this vicious circle, if not broken, may lead to rapid collapse and death.

Replacement therapy is sometimes more successful in saving animals in the late stages of blood loss shock than animals in the late stages of plasma loss shock. This observation raises the question of whether irreversible changes are not more apt to occur in the latter condition.

Compensatory physiological adjustments. Small or moderate reductions of plasma volume do not usually produce the effects described because a number of physiological mechanisms are set in operation which compensate for such losses. It is only when the volume of plasma is seriously depleted that compensation fails and signs of shock develop.

1 The heart promptly begins to beat more forcefully and rapidly, tending to maintain a normal cardiac output and arterial blood pressure.

2 A degree of selective vasoconstriction occurs which shunts the blood from nonvital regions such as the skin through the more vital centers. This compensatory mechanism appears to be less effective in plasmapheresis than in hemorrhage because as has been mentioned vasoconstriction is probably less marked and the blood is much more viscous.

3 A small shift of fluid from the tissues increases the volume of plasma and tends to lessen hemoconcentration at the same time, activation of the red cell stores supplements the depleted blood volume but at the cost of hemoconcentration.

4 The coefficient of utilization of oxygen increases so that the hemoglobin gives up from 60 to 70 per cent of its load of oxygen instead of the usual

15 to 30 per cent. This adjustment is perhaps the most important and effective of these compensatory phenomena.

5. Hyperventilation increases progressively. It facilitates oxygenation of the pulmonary blood and aids in the elimination of carbon dioxide.

These compensatory mechanisms provide a wide margin of safety for normal individuals. That margin is narrowed by plasma loss. When the loss is large compensation eventually fails and anoxia develops. Whenever that happens spontaneous recovery is improbable.

Regeneration of plasma. After substantial but sublethal plasma losses in untreated animals water begins at once to be added to the circulating blood from twenty-four to forty-eight hours may be required for full restitution of the plasma volume. Replacement of the lost plasma proteins likewise starts promptly but progresses slowly. In one experiment, in which 26 per cent of the original plasma was removed and in which the dog was permitted to eat pellets and drink water *ad lib.* the absolute quantity of plasma proteins returned to the original value almost exactly forty-eight hours after the onset of plasmapheresis. When lethal amounts of plasma have been removed the relatively slow process of regeneration is interrupted in its early stages by death of the animal.

SMUEL KARM, M.D.

Hopps, H. C. The Role of Allergy in Delayed Healing and in the Disruption of Wounds. *Arch Surg* 1944 48 438.

It has been estimated that from 15 to 20 per cent of all wounds disrupt following abdominal operations. The disruption of wounds following operation may be due to (1) faulty surgical technique (2) inadequate closure of the wound (3) abdominal distention, coughing, or violent activity on the part of the patient, (4) infection of the wound (5) hypoproteinemia, (6) hypovitaminosis C and (7) constitutional states such as inanition, cachexia, severe anemia and jaundice.

The materials used as antigens in this study were (1) plain surgical catgut, (2) sheep intestine and (3) sheep serum.

Rabbits were used for the experimental studies. They were given varied amounts of material over extended periods of time.

It was brought out from this experimental study that hypersensitivity to catgut could be consistently produced in animals by sheep serum, catgut, or sheep intestine. Catgut stimulates the production of antibodies specific for itself in addition to antibodies which will react with either catgut or sheep serum. The antibodies specific for catgut may also be specific for collagen or mucoprotein. Heterophile antibodies do not react with catgut.

Experiments were carried out to evaluate the effects of hypersensitivity on the reaction of tissues to catgut sutures and on the healing of surgical wounds prepared with catgut. Rabbits were used in this study. Plain and chromicized catgut were used.

Routine sterile surgical technique was used throughout.

Experimentally there were 18 normal rabbits, 10 sensitized to sheep serum, 10 sensitized to sheep intestine, 16 sensitized to catgut, and 6 immunized against heterophile antigen. There was a very wide range in the titers. Biopsies were made at stated intervals. 142 biopsies were studied.

In the rabbits which were hypersensitive to catgut there was evidence of a slightly heightened reaction of the tissues to catgut sutures. There was no appreciable difference between normal rabbits and rabbits sensitized to catgut in the rate of dissolution or digestion of the catgut during the critical period of wound healing.

The healing laparotomy wounds prepared with catgut sutures showed no significant difference between those in normal rabbits and those in rabbits sensitized to catgut. The relative insolubility of catgut sutures is attributed to the absence of significant allergic reactions to catgut in wounds of animals sensitized to catgut.

The effect of local and anaphylactic reaction within the tissues of a healing wound were investigated. Rabbits which were sensitized to either horse serum or egg albumin were used. Abdominal operations were done in the experiment.

Among 37 rabbits with laparotomy wounds, 11 had been sensitized to horse serum and 15 to crystal line egg albumin. Six controls were used. Twenty-five of the 31 sensitized animals received a specific antigen intravenously after operation. Twelve of the sensitized rabbits receiving specific antigen died of anaphylactic shock.

There was no significant difference between the two groups of animals in the reaction to the suture, in the state of the sutures, in the degree of general inflammatory reaction in the plane of incision, or in the amount of edema in the intact tissue.

Microscopically the ratio of macrophages to fibroblasts was considerably greater in animals which had received specific antigen after operation. The biopsy specimens in this group did not show a single fibroblast although macrophages were plentiful nine days postoperatively. In this group the reticulum was finer and there was less collagen than was found in the control animals. The tubing fluid in which the catgut is immersed is quite potent as an inflammatory agent and may produce an Auer reaction.

In normal as well as in sensitized control animals which have received nonspecific foreign proteins, wounds heal without significant untoward reaction. Apparently the most obvious explanation is that a local anaphylactic reaction plays a predominant part. This is a direct or an indirect effect of general anaphylaxis and the local formation of antibodies.

As a precautionary measure, when abdominal operations are performed in the presence of chronic abdominal inflammatory lesions in which such a reaction may occur the abdominal wounds should be thoroughly re-enforced with nonabsorbable sutures.

ROSE and J. BROWN, J. M.D.

Waud R A: The Absorption of Sulfathiazole from Wounds. *Canad Jt Ass J* 1944 51 239

Estimations of the concentration of sulfathiazole at different levels below the floor of wounds have been made at stated periods following the application of different concentrations of the drug and when the latter was incorporated in different bases.

The higher the percentage of the drug in the base the greater was the concentration obtained in the tissues.

The concentration obtained in the tissues beyond 2 to 3 mm. below the surface of the wound is much less than that ordinarily reached when sulfathiazole is given by mouth. This may not be sufficient to prevent the spread of infection and may justify the systemic administration of the drug.

The level of sulfathiazole obtained in the blood when the drug is applied locally approximates that of the tissues situated at a level anywhere between 3 to 7 mm. below the surface of the wound.

The delivery of sulfathiazole out of a water soluble base or an oil in water emulsion takes place quite readily. When incorporated in a fatty or paraffin base and applied to an open wound very little of the drug reaches the tissues. When suspended in a liquid oil the sulfonamide falls out and is deposited in almost pure state on the surface of the wound or dressing.

HOWARD A. MCKNIGHT, M.D.

Brunschwig, A. and Thornton, T. F., Jr.: An Experimental Study of the Lateral Spread of Epidermoid (Squamous Cell) Carcinoma in Man, and the Reaction of Such a Lesion to the Wound Healing Stimulus. *Cancer Res* 1944 4 515

Previous experimental studies in mice and histological studies of specimens from human beings were interpreted to suggest that squamous-cell carcinoma arises by malignant transformation of a segment of squamous epithelium, and not as a result of such changes occurring in one cell or a small nidus of cells. The experimental evidence also was interpreted to indicate that while the principal factor in the increase in size of such lesions was the increased number of cells resulting from continuous mitotic activity, progressive malignant change in the normal epithelium immediately apposed to the malignant epithelium also contributed to lateral spread of the process. This hypothesis admittedly has few adherents today.

Another observation made on mice bearing methylcholanthrene squamous-cell cutaneous carcinoma was that when the carcinoma was bisected and one half of it removed and normal skin was then approximated to the cut edge of the growth by suture with subsequent spontaneous separation of the wound to produce a chronic ulcer, healing of the latter was attempted by epithelial growth from the side of the normal epithelium and not from the margin composed of malignant cells. However the neoplasm did increase in size in the direction away from the cut

edge that is lateral spread took place over the continuously intact margins of the growth.

In a patient presenting a squamous cell carcinoma of the left hand the lesion was bisected and one half was removed together with a semicircular patch of skin. A fresh wound was thus created, one margin of which was composed of malignant epithelium. The course of events in this patient closely paralleled the observations reported in similar experiments with cutaneous squamous-cell carcinoma produced by methylcholanthrene in mice. The wound healing stimulus obtained by the surgical excision of tissue did not locally stimulate the growth of the neoplasm. Indeed the malignant squamous epithelium appeared strikingly indolent toward such a stimulus, and seemed to have lost the property of purposeful proliferation to cover denuded areas. On the other hand, growth was progressive in areas which were undisturbed and the histological findings here were consistent with the hypothesis of progressive cancerization of normal cells as a factor in the lateral spread of squamous-cell carcinomas. The intactness of the original junction zone between malignant and non-malignant squamous epithelium appeared to be a factor contributing to the lateral spread of this type of malignant process.

HOSPITALS MEDICAL EDUCATION AND HISTORY

Lemon H M, Wise H, and Hamburger M Jr: Bacterial Content of Air in Army Barracks: Results of a Study with Especial Reference to the Dispersal of Bacteria by the Air Circulation System. *Am J Med Chic* 1944 6 91

The epidemiological problems which arise in war time as a result of crowding together of large populations in semi-isolated communities are well recognized. The spread of acute infections whose portal of entry is the respiratory tract is particularly enhanced by prolonged close association of large numbers of persons. Although some excellent investigations have been made concerning the influence of various immunological and environmental factors on the incidence of certain forms of air-borne disease in military and civilian populations, little is as yet known concerning the exact mechanism involved in the actual transfer of respiratory disease agents from man to man. While this transfer may in part be accomplished by a direct aerial dissemination of micro-organisms in fine droplets scattered by a sneeze or cough, it has become apparent that there are important secondary reservoirs for respiratory pathogens especially in bedding, clothing and floor dust.

While the major source of the large numbers of air-borne bacteria found in such environments as army barracks is not known, it seems likely that secretions expelled from the human nasopharynx contribute substantially to this heterogeneous bacterial population and certainly constitute the primary source of air contamination with respiratory patho-

gens. This study provides considerable evidence that floor dust, bedclothes, and probably the soldiers' clothing provide a major secondary reservoir of air-borne micro-organisms. Recent studies in wards housing patients with hemolytic streptococcus infections of the throat showed that changes in the number of hemolytic streptococci recoverable from the air paralleled variations in the total bacterial count.

Air entering the room from the delivery ducts is usually considerably lower in bacterial content than adjacent room air at either upper or lower bed levels and dilutes to a greater or lesser degree the concentration of bacteria in the room air. When one considers the enormous increase in air-borne bacteria which occurs each day as a result of the usual routine of dressing, making beds, and the dry sweeping of floors, it becomes apparent that in general the danger of air-borne infection to the soldier population is greater from this local initial pollution of air than from redistribution of disease agents through the air circulation system.

While complete control of the secondary reservoir may not be possible it would seem reasonable to assume that much could be done to diminish the dispersion of bacterial particles, especially from the floor and bedding. Some progress in this direction has already been made. The difference in dust raising between moist and dry floor sweeping is too well

known to require emphasis, but there is less appreciation of the possibilities for dissemination of dust and bacteria from infrequently cleaned blankets.

The concentration of air-borne bacteria in some barracks was found to depend on the number of men present at any one time and on the amount and type of their activity. Even when men had been asleep for several hours there were more bacteria in the air than when the barracks had been vacant for a similar period. The largest number of bacteria was found during the greatest activity of the men, e.g., at times of dressing, bed making, and dry sweeping of the floor.

Group A beta hemolytic streptococci were isolated in small numbers from only 3 per cent of the air samples. In 1 instance a large number of group B type 3 streptococci were recovered near a contaminated bed during bed making. Although the air circulation system was shown to disperse bacteria throughout the barracks under normal conditions of operation it would seem to afford a smaller hazard for spread of air-borne infection than is offered by contaminated dust raised during activities of the men themselves. Studies of this nature provide a new approach to investigation of the spread of acute diseases of the respiratory tract and may serve as means of evaluating special measures employed to reduce air contamination in dwelling places.

INTERNATIONAL ABSTRACT OF SURGERY

VOLUME 80

FEBRUARY, 1945

NUMBER 2

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

EYE

Lancaster W. B.: The Present Status of Eye Exercises for Improvement of Visual Function
Arch. Ophth. Chic., 1944, 32: 167

There is abundant evidence for the general proposition that exercises repetition practice and learning lead to better performance and to the acquisition of skill. Many ocular conditions exemplify this law. Since seeing is only partly a matter of the image on the retina and the sensation it produces and in still a larger part a matter of the cerebral processes of synthesis in which memories play a principal role, it follows that by practice by repetition, and by exercises one builds up a substratum of memories useful for the interpretation of sensations and facilitates the synthesis which are the major part of seeing. Also motor functions are perfected by practice and by learning and reflex pathways are facilitated.

Ophthalmologists have neglected this field, leaving it to irregular half-trained workers while they have concentrated their attention on the primary source of the sensation, the image on the retina.

The author is convinced that there are valuable possibilities in this field awaiting intelligent development. He is skeptical however regarding structural changes which are wrought by exercises other than hyperplasia and hypertrophy of the muscles and the consequent changes induced in the tendons, and perhaps in the bones.

EMIL C. ROSENBERG, M.D.

Brown A. M.: Prostheses for the Eye and Orbit.
Arch. Ophth. Chic., 1944, 32: 308

Two overcorrections are necessary in making a prosthetic eye and lids. The entire orbit should be sculptured slightly higher on the face than it appears on the other side and the conjunctiva should be

Fig. 1. Face after surgical extirpation of the entire orbital contents for retino blastoma. A without, and B with, a prosthesis. The prosthesis had to be designed as a relatively thin sculptured patch to avoid contact with the exposed sinuses.

slightly more viable in the prosthesis than in the normal eye

In this article Brown describes in detail a method which has proved satisfactory in his work but which can be variously modified to meet individual requirements

ERIC C. ROBINSON, M.D.

EAR

Quayle, A. F.: Otitis Externa in New Guinea. *Med J Australia*, 1944, 2: 8.

Quayle states that the incidence of otitis externa in Australian troops in New Guinea is discussed.

The most prevalent type desquamative otitis externa, is described.

It is considered unlikely that the condition is caused by a fungus. Bacteriological examination suggests that it is actually an infection of the skin of the ear canal with *Pseudomonas pyocyaneus* or coliform bacilli. It is seen only rarely in natives.

Treatment is considered, the essentials being the complete removal of desquamated epithelium, and the reduction of swelling by packing

JAMES C. BRASWELL, M.D.

Collins, E. G., and Hughes, K. E. A.: The Treatment of Chronic Suppurative Otitis Media by the Local Application of Penicillin and Other Drugs. *J. Laryngol.*, 1944, 59: 81.

In contrast to acute suppurative otitis media in which penicillin-sensitive organisms are frequent, the initial cultures in chronic otitis media showed the staphylococcus in only 3 ears whereas a coliform bacillus was found in 10 the proteus was found in 13 and diphtheroids in 6 of a total of 26 ears. Cultures were mixed in some instances. Cultures were made by means of a platinum loop introduced into the middle ear through the perforation. These organisms are considered to be not only saprophytes but they are of etiological significance in the persistence of the discharge

Nine patients were treated by the local application of penicillin. After cleansing by intratympanic syringing penicillin was forced into the middle ear by a Politzer bag and then applied at eight hour intervals on a wick leading into the middle ear. Two cases were treated by irrigations following mastoid surgery. Under treatment subsequent cultures showed a frequent contamination of the middle ear by the staphylococcus. Disappearance of the penicillin-sensitive organisms occurred routinely in about five days but recurrence of the staphylococci usually occurred later. Conclusions were that the use of penicillin was disappointing in the treatment of chronic middle-ear suppuration. It has no curative effect on the coliform or proteus bacilli and in cases of the former type an acute otitis externa frequently occurred. In penicillin-sensitive infections the value of the drug is limited because of the mechanical problem of getting contact with the diseased area. Also success cannot be expected in extensive mastoid disease or cholesteatoma.

The use of boric acid in 75 per cent alcohol is found to have a good effect in one-half of the patients with a coliform-bacillus infection. Neither the proteus bacillus nor the staphylococcus and streptococcus appeared to be influenced to any extent. Boric iodine powder gave similar results, although it was more effective in the coliform infections. In both cases the drying effect was considered of primary importance. Several preparations of sodium molybdate were used locally. Of these the molybdate sulfathiazole seemed most suited for application. None of these preparations appeared to influence the proteus cases but some effect was obtained on the coliform cases. The staphylococcus and the proteus bacillus proved in general to be the most intractable to treatment. Other factors such as nasopharyngeal sepsis, the presence of granulomas, and chronicity may have predisposed to failure. The external route of infection of the middle ear in such cases is important and protection against reinfection while healing should be insured.

JOHN R. LINDSEY, M.D.

Atkinson, M.: Ménière Syndrome; Results of Treatment with Nicotinic Acid in the Vasoconstrictor Group. *Arch. Otolaryngol.*, 1944, 49: 201.

Atkinson finds that in cases of idiopathic Ménière syndrome one of two vascular mechanisms is at work, a primary vasodilator and a primary vasoconstrictor mechanism, either of which can produce the characteristic picture. These two groups can be differentiated by means of an intradermal test with histamine. The treatment appropriate to one group is inappropriate and deleterious in the other and therefore accurate grouping is a prime requisite for effective therapy.

Elsewhere the author has published satisfactory results obtained by desensitization in the primary vasodilator group. This article is concerned with the method and the results of treatment in the primary vasoconstrictor group that much larger group in which the response to histamine injected intradermally is normal.

It is believed that in cases of Ménière's syndrome belonging to the primary vasoconstrictor group the disturbance is due to anorexia of the labyrinth caused by vasospasm and that the treatment therefore logically calls for a vasodilator drug. In a series of 110 cases the patients were treated medically exclusively with nicotinic acid by a method described in this report. The attacks of vertigo were relieved or greatly modified in 84 per cent of the cases.

NOAH D. FARRINGTON, M.D.

NOSE AND SINUSES

Colbert, R. M.: Osteomyelitis of the Frontal Bone Treated with Penicillin. *A. N. Otolaryngol.*, 1944, 53: 5.

The use of penicillin in osteomyelitis of the frontal bone gives promise to preclude the radical surgical procedures ordinarily employed, with their attendant deformities.

Penicillin alone cannot be depended upon unless drainage is established surgically. Therefore penicillin definitely has its limitations and must be used as a supplementary measure to surgery or vice versa.

Drainage stops fairly rapidly after primary evacuation of the pus when penicillin therapy is instituted. Constant or frequent local penicillin application is essential even after cessation of the parenteral injections.

At least two weeks of serial sterile cultures of a wound should be obtained before it is allowed to close.

The fact that penicillin has overcome the acute infections caused by staphylococci and the sulfonamide-resistant streptococci indicates that penicillin is an exceptionally potent antibacterial agent.

JOHN F. DEXLER M.D.

PHARYNX

Marino, H. Total Pharyngoplasty (Faringoplastia total). *Prensa Med Argent* 1944 31 1509

Plastic reconstruction of the pharynx is rarely necessary as it is required only after the extirpation of tumors involving the larynx and pharynx. It may be performed at the time of the operation for tumor or at a later date. Generally the latter time is preferred as the patients usually cannot bear the additional operation after removal of the tumor. However the surgeon who performs the first operation should take into account the possibility of the later plastic operation so as to leave the orifices in as favorable a condition as possible and preserve the skin necessary for the flaps.

Two forms of the operation are described and the steps illustrated. In the first, incisions are made at equal distances from the midline and running from the chin down to the esophagotomy opening. The skin flaps are dissected free on each side and united and sutured in the midline and the ends of the tube are sutured into the opening in the floor of the mouth and into the esophagotomy opening. The loose skin is brought over from the sides and sutured over the wound. In the second the incision on one side is made from 6 to 7 cm. from the midline and on the other 3 cm. from the midline. The broader side is dissected free, brought over to the incision on the other side and sutured to it to form the tube. A cervicothoracic skin flap is brought down to cover the bleeding surface and skin grafts are used to cover the two narrow remaining bleeding surfaces.

Two cases in which this operation was performed are described and illustrated with photographs of the patients. In the first case the first type of operation was performed for epithelioma on January 20 1944. The new formed pharynx functioned well up to July 14 1944 when two fistulous tracts opened in it and relatively severe hemorrhage took place. The patient's general condition indicated recurrence of the tumor.

The second operation was also performed for epithelioma of the larynx. Six weeks after removal

of the tumor pharyngoplasty was performed by the first technique. After some time a pulmonary complication developed and the sutures broke down. The plastic operation was repeated by the second technique and at first the neopharynx functioned well. After a time however the patient had difficulty in swallowing and roentgen examination showed a tumor mass evidently cancerous at the cardia. Within a week he died of copious hemorrhage from this tumor. AUDREY G. MORROW M.D.

NECK

Woodson B.: What Can We Do for Myasthenia Laryngis? *Ann Otol Rhinol*, 1944, 53 502

Myasthenia laryngis is a name applied to a morbid entity characterized by asthenia of the phonatory musculature of the larynx, especially the powerful overworked thyroarytenoid muscles.

Constant, excessive use of a very high or a very low pitch is the primary cause for myasthenia laryngis.

Given a complaint of recurrent hoarseness, tired voice and loss of tone with a mirror view of the larynx showing an elliptic chink in the vocal cords we can make a diagnosis of myasthenia laryngis provided we have eliminated other causes.

Prophylaxis is the essence of the successful treatment as a cure can be obtained only in the early stages of the disease. The author has had no beneficial effects from the use of prostigmine.

Relaxation of the muscles of phonation by special exercises is of great value for preventing a recurrence but prolonged absolute silence and rest must always precede any treatment.

The middle register must be used to the exclusion of constant very high or very low pitches in singing or in talking.

JOHN F. DEXLER M.D.

Ferguson G. B.: Hemangioma of the Adult and of the Infant Larynx: A Review of the Literature and a Report of 2 Cases. *Arch Otolaryngol* Chic. 1944, 40 189.

To date, 123 instances of hemangioma of the larynx have been recorded in the available literature. Two distinct classes have been described: the adult cases (116) and the infantile cases (7). One additional case in each class reported herein makes the total 125 cases.

In several instances the diagnosis of hemangioma of the infantile larynx was not made until postmortem examination. However dermal hemangioma, a lesion associated with recurring afebrile laryngeal obstruction may suggest the proper diagnosis of this form of laryngeal hemangioma.

The opinion of the majority holds tracheotomy to be the most suitable method of relieving dyspnea caused by hemangioma of the infantile larynx. Small tumors of the adult type of hemangioma may be removed by forceps. Larger tumors demand a careful selection of approach, which may be made through the mouth, by laryngofissure or by lateral pharynx

gotomy Electrodesiccation, surgical excision, or irradiation may be successful. J M. MORA, M.D

Montserrat, J. L.: Epithelioma of the Larynx (Epithelioma de la laringe) *Rev As med. argent* 1944, 58 670

This is a statistical review of the subject of epithelioma of the larynx, illustrated with graphs, tables and photomicrographs of the histological findings in a number of the cases. The author made a study of 350 cases of tumors of the larynx 180 of them from biopsy material 42 from autopsies, 13 from museum pieces and 15 from operative material. Among the 198 cases in which the sex was given 190 were men (95.95 per cent) and 8 women (4.05 per cent). Among the 197 cases in which the age was given the youngest patient was twenty three years of age and the oldest eighty 36.55 per cent of the patients were between fifty and fifty-nine years of age 30.46 per cent between forty and forty-nine and 15.73 per cent between sixty and sixty-nine.

Among 10,830 autopsies in the Instituto Telémaco Suximi there were 3,021 cases of cancer of which 42 were in the larynx therefore cancers of the larynx were found in 0.38 per cent of the total number of autopsies and in 2.1 per cent of the total number of cancers. Among 543 cases in which histological examinations were made 82.3 per cent were prickly-cell epitheliomas divided into sub-varieties depending on the degree of differentiation and atypia 3.7 per cent were epidermoid 16.45 per cent had horny pearls, 2.87 per cent were dyskeratotic, 44.03 per cent were moderately differentiated and 15.22 per cent were only slightly differentiated.

Intermediate pavement epitheliomas constituted 5.34 per cent basal-celled 1.23 per cent and finally atypical cases 10.18 per cent.

Topographically they were divided into pure laryngeal tumors laryngopharyngeal tumors, and laryngoglottic tumors. The first group were divided into supraglottic, glottic, infraglottic, and generalized. Of the total, 69.5 per cent were supraglottic and were divided into epiglottic (42.75 per cent) cord-ventricular (18.14 per cent) and aryepiglottidean fold (8.24 per cent). The glottic tumors made up 26.3 per cent of the total and included those of the vocal cords (18.55 per cent), and those of Morgagni's ventricular cavity. The infraglottic tumors made up 2.3 per cent of the whole, and the generalized forms 2 per cent.

AUGUST G. MORAN, M.D

Howes, W. E., and Plateau, M.: Carcinoma of the Larynx: A Review of Treatment and End-Results at the Brooklyn Cancer Institute. *Arch. Otolaryng. Chic.*, 1944, 40 133

Only carcinoma arising on the vocal cords (intrinsic) was observed to be amenable to surgical treatment in this series of cases. Radiation therapy was shown to be of value in the treatment of both carcinoma arising on the cords and carcinoma of the extrinsic structures of the larynx. Of 68 men and 3 women with lesions proved to be carcinoma of the larynx, who were admitted to the Brooklyn Cancer Institute from 1934 through 1943 17 are living. Of the surviving patients, 12 had carcinoma originating in the intrinsic larynx, and 4 in the extrinsic larynx.

NOAH D. FARRINGTON, M.D

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Elkington J St. C. Prognosis of Peripheral Nerve Injuries. *Proc R Soc M, Lond* 1944 37 547

The prognosis with regard to recovery in peripheral-nerve injuries is discussed relative to the individual nerves

The radial nerve has been found to regenerate more rapidly and completely than any other peripheral nerve. While recovery may not be complete, very useful function of the involved muscles returns in a good percentage of cases

The ulnar nerve is considered the most disappointing and unsatisfactory from the standpoint of recovery of function following injury and repair. Although a fair degree of function may return in the long flexors supplied by the ulnar nerve there is often little or no recovery in the hand muscles

The median nerve shows a recovery level between the radial and ulnar nerves. Here again, recovery in the long muscles of the forearm is much better than recovery in the small hand muscles supplied by the median nerve, which, as a rule is incomplete and functionally unsatisfactory. Fair degrees of recovery in the sensory mechanism of the median nerve results in a good percentage of cases particularly in injuries nearer the wrist.

The sciatic trunk, in the author's experience has not shown the degree of recovery one might expect following what appears to be a satisfactory anastomosis. Recovery in the gastrocnemius and soleus and tibialis posterior muscles is fairly good but muscles of the anterior tibial group are rather disappointing and recovery in these is not frequently seen. Sensory recovery has resulted in rather crude sensation to pinprick and temperature over the sciatic distribution. The mechanism of the foot is usually seriously affected as a result of the incomplete recovery in muscular function.

The peroneal nerve has recovered poorly from the motor standpoint on the whole despite a fair recovery of sensation. The tibial nerve shows a return of crude sensibility in the sole muscular recovery seldom proceeds beyond the proximal muscles of the calf

The author concludes from these observations that the smaller the muscle and the more delicate its function, the less likely it is to make a satisfactory functional recovery after a period of denervation.

The factors modifying the average prognosis in common peripheral-nerve injuries are

1. Wounds which are complicated by heavily infected compound fractures and severe destruction of the soft tissues as well as considerable loss of continuity of the nerve.

2. Date of suture this factor may be complicated by infection and it is suggested that the minimum of three months be allowed to elapse between com-

plete healing of the wound and an attempt to suture the nerve

3. Individual factors There is some reason to believe that nerve regeneration (as with any other process of healing) may vary in different individuals. The only factor here considered was that of age and the observations would indicate that the younger the patient, the better the outlook as far as nerve recovery is concerned

Recovery of function in the part enervated by the nerve is stressed. The preservation of the most complete possible degree of mobility of every part of the limb affected is important in preserving the maximum of ultimate function. Excess splinting often results in unnecessary joint stiffness and considerable functional loss. Psychotherapy and occupational therapy are also of importance in effecting the maximum degree of rehabilitation

Rehabilitation for Army service in the British Army has been low in patients who have had peripheral nerve injuries sufficiently severe to require exploration. Apparently over 10 per cent of the enlisted men in this group could be returned to some type of Army service in a lower category

HOWARD A. BROWN M.D

Learmonth J R.: Personal Experience of Exploration and Re-Exploration of Injured Nerves. *Proc R Soc M Lond* 1944 37 553

The author has set down certain indications for exploring an injured nerve irrespective of the clinical findings. These may be listed as follows (1) previous long-continued sepsis in the wound (2) a nerve lying at the bottom of a healed trough wound (3) a history of an unusually severe bleeding from a muscle mass (4) enclosed crushing types of injury (5) a nerve or nerves and the main artery to an extremity having been injured at the same level (6) two or more nerves of the same limb having been injured and (7) persistent pain or persistent hyperhidrosis in the cutaneous distribution of the injured nerve.

Decision for or against excision and suture in cases of partial division is often difficult. It is advised that these be let alone when there is a fair degree of motor or sensory function in the median or ulnar nerve groups.

Skin grafting over the areas (either split graft or full thickness graft) should precede operative repair of the involved nerve

Conservative treatment is advised when there has been gross loss of tendon and muscle tissue and it is obvious that useful movements cannot be restored

Re-exploration of a nerve previously operated upon depends upon the interval which has elapsed since suture, the level of the lesion, and the absence of any evidence of nerve recovery after an adequate time has elapsed. Postganglionic sympathectomy

has been tried in a number of cases in an attempt to decrease the total number of axons competing for the tubes in the distal segment following end-to-end anastomosis. No estimate of results is given at this time.

HOWARD A. BROWN, M.D.

Botterell, E. H., Keith, W. S. and Stewart, O. W.: Results of Surgical Treatment of Sciatica Due to Herniation of an Intervertebral Disc in Canadian Soldiers Overseas. *Canad. M. Ass. J.* 1944, 51: 20.

The authors report the results of a follow up study on 51 cases of herniated nucleus pulposus in which an attempt was made to ascertain the outcome of operation on the patients. The personnel, however, was entirely that of the Canadian Army and military cases do not react the same as those in civil life. It is emphasized that careful selection of the cases for operation is extremely important, and that it is quite impossible to operate in every case in which the symptoms appear. In the majority of the cases, conservative treatment was administered for a period of three weeks, and the patients were observed for any improvement under this type of management. In some of the cases the diagnosis was supported by pantopaque or oxygen myelograms. Operation was never done on patients who appeared to be emotionally unstable, or who had some physical defect. It was found very important to ascertain whether or not the patient was desirous of carrying on in the Army and in the event that he did not wish to do so operation was not performed. The operative procedure is said to have been the same as that carried out by neurological surgeons.

Postoperative care consisted in keeping the patient in bed for two or three weeks and reconditioning was commenced during the last few days in bed in the form of tension exercises. A few days later restrictive physical exercises were started and the range of movement was increased gradually until the patient was able to carry on in the back class. The entire procedure was carried out under the supervision of the surgeons.

The article is accompanied by tables which show the breakdown of the patients who were investigated.

There were approximately 100 men in the original group. All of the 51 patients who form the basis of this study had an operative diagnosis of herniation of a lumbar intervertebral disc. Twenty nine men were returned to full duty, 14 were returned to sedentary duty and 8 were unfit for military duty.

ARTHUR VERNSTROMER, M.D.

De Rezende, N.: Nerve Grafts from Cadavers in Human Surgery (*Enxerto de nervos do cadáveres em cirurgia humana*). *Rev. brasil. cir.* 1944, 3: 7.

The author discusses the use of nerve grafts from cadavers in the repair of nerve injuries. Nerve grafts have been used chiefly in military surgery. The graft must be taken from the cadaver not more than twenty four hours after death. The technique of taking the graft and of fitting it into the nerve to be

treated is described. The author uses a 50 per cent solution of gum acacia to cement the graft into the lacerated nerve. After the operation the patient is given subcutaneous or intramuscular injections of cholinergic drugs such as vitamin B and strychnine. These cholinergic drugs have the property of stimulating the healing of wounds of nerve tissue. Three clinical cases are described in which the results were excellent. The histories of these and 21 other cases which the author treated will be read at the next medical Congress in the United States.

In the after treatment electrotherapy, hydrotherapy, physical therapy, immobilization, and light massage are useful. References are given to American journals in which these experiments are published.

AUDREY G. MORGAN, M.D.

BRAIN AND ITS COVERINGS CRANIAL NERVES

Grimson, K. S., Kernodis, C. E., Jr. and Hill, H. C.: Hypertension. *J. Am. M. Ass.* 1944, 26: 12.

It is well realized that sympathetic surgery for hypertension requires a careful evaluation of each case. The patients who apparently receive the greatest amelioration are those in whom the condition is due to a vasomotor instability, and to which the term "neurogenic hypertension" has been applied. Since the cases due to renal factors have not been relieved, the authors believed it important to evaluate their diagnostic criteria of the effect of rest, sedation, and anesthesia. To this end, a series of tests have been performed on experimental neurogenic hypertension in dogs.

The effect of activity rest, and natural sleep on blood pressure was examined in a group of 4 normal and 4 neurogenic hypertensive dogs. As would be expected a drop in blood pressure occurred during rest and sleep in the normal dogs, and also in 3 of the hypertensive dogs, but in the latter 3 cases it never reached the low levels occurring in the normal dog.

Sodium amytal averaging 0.3 gm. per dog, had no specific effect on the blood pressure of either normal or hypertensive dogs.

Sodium pentothal anesthesia was induced in 5 normal dogs, and in 6 neurogenic-hypertensive and 7 renal hypertensive dogs. This was administered intravenously in a 2.5 per cent solution until pain reflexes were abolished. The results in the normal and renal hypertensive dogs were variable, a rise in blood pressure occurred in about half of the dogs, and a fall occurred in the rest. However 5 of the 6 neurogenic hypertensive dogs revealed a decided drop in blood pressure.

Chloralose anesthesia had no definite effect in either the controls or the neurogenic-hypertensive dogs. Ether anesthesia had little effect on the blood pressure of the normal dogs, but in the neurogenic hypertensive dogs a definite drop in blood pressure occurred in all.

The conclusion is reached that sodium-pentothal or ether anesthesia produced a drop in the blood

pressure of neurogenic hypertensive dogs to approximately the same levels as did rest and natural sleep. Sodium-amytal or chloralose had no specific effect.

The records of 20 patients treated by paravertebral sympathectomy and tested preoperatively for the effect of sodium amytal and rest on their hypertension were reviewed. Although these tests may aid in the evaluation of the hypertensive patient, their importance should not be overemphasized for the results may often be variable and misleading.

JACK I. WOOLY, M.D.

Everts, W. H., and Woodhall, B. The Management of Head and Spinal Cord Injuries in the Army. *J. Am. M. Ass.* 1944, 126, 145.

Head injuries make up 6 per cent of battle casualties. Of these more than three-quarters are closed head injuries with or without simple skull fracture and the remainder are open head injuries.

Closed head injuries receive conservative therapy. During the acute phase in the first seventy-two hours the patient is placed on a modest fluid intake (1,500 to 2,000 cc.) and a light diet. Unless indicated, a lumbar puncture is not done until after from forty-eight to seventy-two hours when it may be desirable to know the pressure and whether or not the fluid is blood-stained. Sedatives are used with caution as they may produce stupor or mask bleeding. Hypertonic solutions are used only when edema is evident and producing symptoms a day or two after the injury. Normal serum albumin is probably the best hypertonic solution. Unless indicated roentgenograms of the skull are not taken until after the first day or two. In some of the forward stations, closed head injuries have been evacuated in ambulatory fashion as soon as the patient was clearly conscious. In general the patient is kept in bed for two or three weeks or more, according to the severity of the injury as estimated from the duration of the period of unconsciousness, the degree of disturbance of the temperature, respiration, and pulse, pupillary abnormalities and focal neurological signs. In a number of the milder head injuries latrine privileges were permitted after the first twenty-four to seventy-two hours and then there was a graduated program of activity over a period of the next ten days with return to light duty in about two weeks and full duty in six. The results in this group were gratifying and the incidence of post-traumatic syndromes was especially low.

All patients with head injuries receive a most painstaking neurological survey in the general hospitals including electro- and pneumoencephalography, mental tests and psychiatric studies. Of a group of 131 patients with closed head injuries 79 per cent returned to full duty after an average hospitalization of twenty-five days, 15 per cent developed post-traumatic syndromes and 6 per cent were still being rehabilitated.

Open head injuries comprise about one-fifth of all head injuries. In two series the mortality was respectively 33.6 per cent and 15 per cent for pen-

etrating wounds and 1 death in 208 and 3 deaths in 224 nonpenetrating wounds. The most important complication is infection, particularly in those cases in which early and complete débridement of the cranial wounds has not been accomplished. In two series fatal infection after operation supervened in 3.7 per cent and 10.8 per cent respectively. Chemotherapy with sulfonamides in fresh wounds does not reduce the incidence of infection when débridement is delayed.

Two new substances, penicillin for the control of infections and fibrin foam for the control of hemorrhage are now receiving clinical trial. In brain abscess surgical drainage must be continued during the period of penicillin therapy as penicillin alone is inadequate. Skull defects in otherwise recovered individuals may be repaired with tantalum plates 0.015 inch in thickness by inlay or other techniques. Before the skull defect is repaired, evaluation of the existing cerebral scar is attempted. Post-traumatic epilepsy has been of minor significance in these cases. Records of cortical electrical activity taken through the tantalum plates are unchanged when compared with preoperative records.

Spinal-cord injuries constitute less than 1 per cent of all battle casualties. Three-fourths were caused by foreign bodies and the other fourth by fracture. Incomplete lesions of the cord were more common than complete lesions (this statement referring to functional and not to anatomic lesions). Sensory examination was the most accurate guide as to the level, and bladder signs were the best guide as to the severity of the lesion; the latter also were good indications for the urgency of operation. Operation was performed in 31 cases, 12 lesions were complete and 19 incomplete. There was improvement in all incomplete lesions operated on and no improvement in any of the complete lesions. Of those in which operation was not performed, 1 incomplete lesion but none of the complete showed improvement. The reasons for operation on complete lesions were cerebrospinal fluid leaks, the presence of block, and x-ray evidence of cord compression. There were 4 deaths all in cases of complete lesions. Death was due to pneumonia and lung abscess in 1 case and to pulmonary emboli in 2 cases; the cause of death in the fourth patient was not ascertained as there was no autopsy. Travel is damaging to cord injuries.

The use of the Stryker turning frame has prevented the occurrence of fresh decubitus ulcers and facilitated the nursing care of the patient. Suspension of the feet, freeing them from contact with the bed clothes and frequent and effortless turning of the patient promote healing of the pressure areas. Change of the bed linen offers no problem on such a frame.

DAVID J. IMPASTATO, M.D.

Grollman, A., and Rousseau, J. P.: Metabolic Craniopathy: Hyperosteosis Frontalis Interna. *J. Am. M. Ass.* 1944, 126, 213.

The authors report a study of 40 patients with the diagnosis of metabolic craniopathy or hyperostosis

frontalis interna. The diagnosis was based upon the history, physical examination, and laboratory studies, and was confirmed by roentgenological findings. These patients were seen at the North Carolina Baptist Hospital, Winston Salem, during the past two and one-half years, and comprised part of a group of 78 patients who on roentgenological examination of the skull, were found to have the calvarial hyperostosis suggestive of this disorder.

The highest incidence as to age distribution occurred in the fourth and fifth decades. The actual age of onset is unknown, however it must have been much earlier in view of the rather benign and insidious character of the condition. There was but 1 male among the patients.

The symptomatology may be grouped into any one or more of the following categories: metabolic, endocrine, hypertensive, or neuropsychiatric. The latter group contained the largest number of patients, but the complaints were extremely variable and did not conform to any definite syndrome. These ranged from minor neurotic complaints to hysteria and major psychosis.

Twenty-three of the patients had metabolic disturbances consisting chiefly of obesity. The basal metabolic rate and blood-cholesterol levels were essentially normal. Hyperglycemia was found in only 3 cases, and in 2 of these it was of a very mild degree. The principal endocrine disturbances were related to abnormalities of menstruation not associated with recognizable pelvic disturbances. Hirsutism was prominent in 12 patients. The 17-ketosteroid excretion was normal in all patients examined in this regard. Hypertension was present in 16 patients, and, although identical with benign hypertensive cardiovascular disease was thought to be another manifestation of the metabolic cranio-pathy.

The typical roentgenological picture of the skull was a hyperostosis of the inner table of the frontal bone. The outer table and thus the external configuration, remained unaltered. Although this was true in all of the cases in this report, other areas of hyperostosis may occasionally be seen in the base of the skull, and in the parietal areas or there may even be diffuse calvarial changes. The frontal bone may attain a thickness of as much as 5 cm. on x ray measurement. Although no specific worth while treatment is known, several of the patients responded favorably to irradiation of the pituitary hypothalamic area. Others so treated had no amelioration of their symptoms.

Despite the absence of a known pathological basis it is the authors opinion that metabolic cranio-pathy is a specific clinical entity of relatively frequent occurrence.

JACK I. WOOLR, M.D.

Dowling, E., Viale, S. M. and Legarreta, C. C.: Peritumoral Meningiomas (Meningiomas peritumorales). *Rev. med. chir. pat. fem.*, B. Afr. 944, 1939.

The author discusses a group of meningiomas originating near the torcular Herophili and compress-

ing the occipital lobe. Two cases are described. The first was in a woman forty-six years of age who for three months had complained of dizziness with a tendency to fall forward. At the same time she began to have difficulty in finding words to express her thoughts. Soon afterward she noticed falling vision and frontal headache followed by nausea and vomiting. Examination of the eyes showed right lower homonymous quadrantanopia with intense edema of the discs and peripapillary hemorrhages. Ventriculography showed displacement of the ventricular system to the right and forward displacement of the posterior part of the left lateral ventricle, the capacity of which was reduced. Operation showed a tumor of the region of the torcular Herophili, which was removed. The patient was well for four months when she returned with a recurrence of symptoms and a second operation showed a tumor in the same region twice as large as the original one. Some months later she returned with another recurrence of the symptoms and inspection showed tumor infiltration of the scalp. She died two months later. The tumor was of the angioblastic type.

The second patient was a man of fifty who had intense pain in the right temporo-occipital and maxillary regions, dizziness, headache, and vomiting. He had once fallen in a canal because he thought there was a bridge across it where none existed. It presented right homonymous hemianopia which did not spare the macular bundle. This, the left hemiparesis, and the electroencephalographic examination indicated that the tumor was not confined to the occipital region but extended into the temporal region as well. A large vascular tumor originating in the peritumoral region was removed. The patient recovered and is well fourteen months later.

The difficulties of diagnosing the occipital localization of these tumors is emphasized. The two leading symptoms of occipital localization are homonymous hemianopia and visual hallucinations. In temporal tumors the visual field defect is supposed to begin in the upper quadrants, while in those of the occipital region it begins in the lower quadrants but often the patients do not come for examination until the homonymous hemianopia is completely established. The visual hallucinations in occipital tumors are supposed to be merely dots and stripes of bright light, while there are more elaborate hallucinations in temporal tumors. However in the author's second case the man believed he saw a bridge over a canal and as a result walked into the canal. The coexistence of cerebellar symptoms indicates a occipital tumor. It is possible that the preservation of the macular bundle and consequently of central vision so frequently seen in occipital lesions masks the falling vision to a certain extent and explains the great edema of the disc and even secondary atrophy which are observed when the patients first come for examination. It is certain that the diagnosis of tumors of the occiput is not on as firm a foundation as that of tumors in other parts of the brain, and generally only a presumptive diagnosis of peritumoral

tumor can be made. About half these tumors are angioblastic and, therefore, particularly malignant.

AUDREY G. MORRAN, M.D.

Hortega, P. del R.: Study of the Oligodendrogliomas (Contribucion al conocimiento de los oligodendrogliomas). *Rev. As. Med. Argent.* 1944, 38, 511.

This is a detailed discussion of the cell structure of the oligodendrogliomas illustrated by photomicrographs of these tumors in the brain, olfactory bulb and optic chiasm. Bailey and Cushing discussed these tumors although they were not sure that they had identified the cells with the oligodendrocytes described by Hortega in 1921.

These tumors occur chiefly in the brain. They are of slow growth, relatively benign and made up of small cells with a round nucleus and a clear cytoplasm. There are four types of normal oligodendrocytes, only two of which, the first and fourth, are found in these tumors. The first is a round cell and the fourth an elongated or Schwannoid type. Contrary to what occurs in the normal cell, the neoplastic oligodendrocyte may adopt different forms and pass from the round to the stellate shape. Among the oligodendrogliomas which the author observed he rarely found cells of a single type; there were not only small round cells but others with numerous processes. Among the tumors that he describes there were at least two types with cells which might be considered oligodendrocytes. In the first most of the cells were undifferentiated morphologically but there were isolated cells or small groups of cells that had the appearance of astrocytes. In the second type most of the cells were differentiated but did not have the appearance of true astrocytes. The latter were cells which developed to a certain extent according to the rules followed by normal cells but never became astroblasts or astrocytes. It is possible that in a single tumor there may be areas that can be classified as astrocytomas while other parts are distinctly oligodendrogliomas.

It is an interesting fact that the only slightly differentiated oligodendrocytes may make the tumor more malignant as they become detached from the tissue and fall into the spinal fluid. They are carried to distant parts and produce metastases. One of the tumors, an oligodendroglioma of the olfactory bulb, followed this course.

SPINAL CORD AND ITS COVERINGS

Shenkin, H. A., and Alpers, B. J.: Clinical and Pathological Features of Gliomas of the Spinal Cord. *Arch. Neurol. Psychiat. Chic.*, 1944, 53, 87.

A correlation of the pathological and clinical features of 27 verified cases of intramedullary gliomas of the spinal cord is presented and an attempt is made to clarify the diagnostic characteristics of these tumors. The cases were evenly distributed as to age from the second to the sixth decade and the tumors occurred predominantly in males. The average dura-

tion of the symptoms in all cases was twenty months. The duration of the symptoms appeared to increase, the lower the position of the tumor in the spinal cord and ependymomas were found to have a distinctly longer course than astrocytomas. It appears therefore that the duration of symptoms cannot be used as a safe criterion in the differential diagnosis of intra and extramedullary tumors.

The first symptom was pain in 16 of the 27 cases, weakness in 7 and paresthesia or numbness in 5 cases. The location of the tumor was apparently of no significance so far as the type of onset was concerned except that with tumors of the cauda equina the onset was always with pain. Severe injury preceded the onset of the symptoms in 6 cases. Because of the conflicting evidence concerning the presence or absence of pain with intramedullary tumor the occurrence of this symptom cannot be used as a differential point in the diagnosis of intra and extramedullary growths. Pain occurred in 23 of the 27 cases and was the outstanding symptom in 18 cases. Root pain was more common than spinal pain while tract pain was least common.

Paresthesias and other sensory symptoms were noted in 23 cases. In all 27 cases there were motor symptoms or signs of varying degree in 9 of which they initiated the picture. Objective sensory changes were present in 14 cases. Sensory dissociation was definite in 8 cases. The objective sensory changes with tumors of the caudal region were insignificant and not in proportion to the subjective sensory complaints. With tumors of the other regions the sensory changes appeared to be significant and of great importance for the accurate horizontal localization of the tumor in the spinal cord. With certain reservations the presence of a waltz-type of sensory disturbance or relatively greater alteration of sensation in the more proximal dermatomes is indicative of an intramedullary process. Less reliable is the dissociation of sensory loss. An indefinite level for sensory loss is of little practical importance in the localization of a spinal tumor within the substance of the cord. The presence of a Brown-Sequard syndrome does not eliminate definitely the possibility of a primary tumor of the spinal cord and contrary to the frequently expressed opinion failure or absence of involvement of the anogenital region does not appear to be characteristic of intramedullary tumors. In 16 cases symptoms of sphincter disturbance were present. Signs referable to the cranial nerves were frequent with tumors which extended as high as the second cervical segment.

In 25 cases manometric studies were made. Complete block was shown in 13 and partial block in 8. In 4 cases with normal cerebrospinal fluid dynamics the thoracolumbar portion of the cord was involved. The most frequent abnormality of the spinal fluid was an increased total protein, the highest values being associated with tumors having the greatest longitudinal extent. Xanthochromia was recorded in 12 instances but the cell count was normal in most cases.

A study of the many contributions concerned with the intramedullary gliomas indicates that the clinical pictures of intra and extramedullary tumors are much the same and that the several points cited for the differentiation of the two conditions are only relatively significant. Despite this the distinction is not clinically difficult when all points are considered. The most distinctive feature of an intramedullary growth is a greater disturbance of sensation in the proximal segments than in the more distal segments.

SYMPATHETIC NERVES

Engel, G. L., Romano, J. and McIlwain, T. R.: Vasodepressor and Carotid-Sinus Syncope: Clinical Electroencephalographic and Electrocardiographic Observations. *Arch Int M* 1944, 74, 100.

Syncope or fainting is a transient reaction and it is, therefore, quite difficult to obtain satisfactory reports, especially electrocardiographic and electroencephalographic tracings of patients during an attack. In this article, however, the various types of attacks which can be induced were studied by means of electrocardiograms and electroencephalograms. The work was done in the department of psychiatry in the University of Cincinnati College of Medicine. Eighteen patients and volunteer subjects were studied. Electroencephalograms and electrocardiograms as well as clinical observations were made of the patients simultaneously and suitable complete records are appended to the original article, as well as the clinical data on each case.

Syncope was induced by a variety of means including venipuncture, distention of the duodenum, colon, rectum, or vagina, hyperventilation and the carotid-sinus reflex. The mechanisms of the various types of syncope is discussed. In some instances the distention of the colon was induced by giving large enemas, by inserting a rubber bag and inflating it, or in 1 instance by inserting a duodenal tube and inflating a rubber bag in it. These phenomena are carefully described.

There are two main types of fainting which were discussed: syncope of the vasodepressor type associated with pain, distention of the viscus, venipuncture and other manipulations, and syncope induced by manipulation of the carotid sinus. It was found that vasodepressor syncope could be induced by a variety of stimuli. The surroundings and psychic reaction of the patient are especially important in this variety of syncope. Psychological experiences, such as seeing blood, viewing mutilations, hearing bad news or other emotional reactions strongly predisposed certain people to vasodepressor syncope. Furthermore the vasodepressor reaction may continue for a considerable time after withdrawal of the original stimulus. There results a disturbance in the circulatory apparatus in which there is a discrepancy between the volume of the vascular bed and the volume of the circulating blood. In most instances

this can be overcome by gravity, hence, the advantage of collapse and falling to the ground. Certainly the erect posture of the patient was unsatisfactory.

The symptoms and signs of vasodepressor syncope, such as pallor, sweating, weakness, nausea, and faintness are secondary to the fall in arterial blood pressure. This was shown by the prompt improvement in a recumbent position, when the blood pressure rose. Even though the persistence of the functional disturbance could be repeatedly demonstrated by returning the subject to the erect position, in some cases the disturbance continued even with the patient in the recumbent position and the authors find it difficult to say at what stage this condition of persistent hypotension passes into a condition which could be described as primary shock. Unconsciousness in vasodepressor syncope is a late phenomenon and occurs only when the arterial blood pressure has been extremely low.

Recovery from vasodepressor syncope may take place in the erect position, but the subject should be encouraged to lie down and, especially, to move the legs with a certain amount of activity and then should be gradually restored to the erect position. However, he should be warned against remaining motionless standing, or even sitting. The old remedy of slapping the face and throwing cold water on the individual has a sound theoretical foundation as it provokes resistance and muscular activity.

With regard to the electroencephalographic findings in these cases, slow waves invariably appeared in the electroencephalogram in any case of syncope which was allowed to progress to unconsciousness. Furthermore recovery from complete unconsciousness always took place in a certain definite way: (1) the waves decreased in amplitude, (2) there was random low voltage and fast activity and (3) low amplitude regular waves occurred which rapidly reached alpha frequency. These stages, occurring over a course of seconds or minutes are essentially the same as those observed during recovery from delirium over the course of days or weeks. In 3 cases of the cerebral type of carotid-sinus syncope the development of contralateral focal neurological signs and symptoms without loss of consciousness was associated with abnormal waves from the ipsilateral cortex.

Another report which is being prepared by the authors will show that hysterical syncope is not accompanied by any slow waves in the electroencephalogram. Hyperventilation was also used to produce syncope, again with the appearance of slow waves in the electroencephalogram.

ADRIEN VERBROEGHE, M.D.

Smithwick, R. H.: The Surgical Treatment of Hypertension: The Effect of Radical (Lumbodorsal) Splanchnicectomy on the Hypertensive State of 154 Patients Followed Up For from One to Five Years. *Arch Surg* 1944, 49, 40.

The author has thoroughly reviewed his series of 156 hypertensive patients operated upon during the

past five years. The lumbodorsal splanchnicectomy as originally advocated and now known as the Smithwick sympathectomy was used. The extent of the denervation varied but in all of the cases the great splanchnic nerves were removed from the celiac ganglion to at least the midthoracic level. No correlation has been drawn in this report between the extent of the operative procedure and the results. The operative mortality rate was 2.8 per cent.

A gross tabulation of the results of splanchnicectomy has been made from changes of the diastolic blood pressure. This is shown in Table I.

The period of reduction in blood pressure following operation is still unknown. However, a comparison between two-thirds of the patients followed up for approximately two years and one third of the patients followed up for approximately three years has not revealed a significant difference.

By further dividing the patients on the basis of the pulse pressure three types of hypertension have been derived. Type I is that group having a pulse pressure of less than one half the diastolic blood pressure. Type II having a pulse pressure up to 10 mm. more than one half the diastolic pressure and Type III having a pulse pressure 20 mm. or more greater than one half the diastolic pressure. This grouping has given a very interesting and helpful prognostic criteria in that the patients with the smallest pulse pressure, on a percentage basis, had the best results while those with the highest pulse pressure had less favorable results.

The sex factor is of interest since 84.8 per cent of the women and only 71.8 per cent of the men were definitely benefited.

A point worthy of further study is the correlation of renal pathology with results of the operation. Renal biopsy material of 100 patients was classified and grouped into that of patients with none to mild changes and that of patients with advanced degrees of arteriolar disease. However, there was essentially no difference in response to surgery. An unusual finding was that of 11 patients with pyelonephritis, 90.1 per cent had excellent results while 100 per cent had some benefit. Glomerular filtration was reduced about 20 per cent immediately after operation, however it returned to normal within one year. Studies of kidney function revealed that the majority of patients had some improvement after operation as adjudged by clearance of sediment, disappearance of albumin and improvement in concentration.

Hypertensive funduscopic changes were correlated with the splanchnicectomy and it was found that in the more advanced cases improvement of the fundus picture was more likely to occur. Among the most severely damaged cases, improvement occurred in 100 per cent. It should be noted that of the group of patients who did not obtain a satisfactory drop in blood pressure, 48.2 per cent revealed an improvement in their eyegrounds.

An electrocardiographic study before and after operation revealed an improvement in 63.5 per cent of the records of two-thirds of the patients who had

TABLE I.—EFFECTS OF LUMBODORSAL SPANCHNICECTOMY ON THE BLOOD PRESSURE OF ONE HUNDRED AND FIFTY SIX PATIENTS FOLLOWED FROM ONE TO FIVE YEARS*

Result group	No. of patients	Percentage	Effects of lumbodorsal splanchnicectomy	
			Effect on diastolic blood pressure	Average reduction
	64	65 70.4	Lowered 20 mm. or more	6/43
	32		Lowered 10 to 20 mm.	44/34
	8		Lowered 1-9 mm.	7/3
	7	9 20.6	Lowered 1-9 mm.	0/5
	5		Increased	(Increase) 8/
Total	56			

Average three followed, twenty-two and half months. In this table the results are considered as a whole. They have been subdivided into six smaller groups according to type of blood pressure and sex (Tables 2, 3 and 4). When subdivided in this fashion, the results are much more helpful in indicating the outlook for the individual patient than when they are undivided, as in this table.

definitely abnormal records. Again it is worthy of note that of the patients not obtaining satisfactory blood-pressure responses, 55.9 per cent showed an electrocardiographic improvement.

It therefore appears that the present available methods of study do not give full value to the beneficial results derived from splanchnicectomy as measured by a change in blood pressure.

JACK I. WOOLR, M.D.

Rojas F. Smithwick, R. H. and White, P. D.: Nonspecific Major Operations and Lumbodorsal Sympathectomy. *J Am Med Ass* 1944, 126: 15.

In 1939 Volini and Flaxman followed the course of the blood pressure of 17 hypertensive patients operated on for different reasons not related to their hypertension. They observed in almost every case a postoperative reduction in the blood pressure and concluded that the blood pressure reduction attributed to nerve resection was actually due to the conditions brought about by the major operations. On this basis they denied the specific effect of sympathetic-nerve resection on hypertension. In 1943 Adamson and Dubo arrived at similar conclusions.

With the purpose of checking these opinions the authors studied the records of 100 hypertensive patients who had been submitted to various major operations (Group 1) and of another 100 hypertensive patients who had submitted to bilateral lumbodorsal sympathectomy by the procedure of Smithwick (Group 2).

This study shows that nonspecific major operations produce some immediate reduction of the blood pressure of hypertensive individuals (Table I). How

TABLE I—IMMEDIATE EFFECT OF OPERATION

	No results	Moderate reduction	Pronounced reduction
Group 1. Immediate reduction (up to 6 months after the operation)			
Systolic pressure	49%	40%	2%
Diastolic pressure	60.3%	27%	2.6%
Group 2. Immediate reduction (4 days after the second stage of the operation)			
Systolic pressure	3.3%	24.4%	72.3%
Diastolic pressure	8.8%	37.7%	53.5%

TABLE II—CONDITION SIX OR MORE MONTHS LATER

	No results	Moderate reduction	Pronounced reduction
Group 1. Late reduction (more than 6 months after the operation average period of observation, months)			
Systolic pressure	82.7%	17.3%	0%
Diastolic pressure	36%	14%	0%
Group 2. Late reduction (more than 2 months after the second stage of the operation average period of observation, 30 months)			
Systolic pressure	9.6%	28.1%	62.3%
Diastolic pressure	7.6%	36.1%	56.3%

ever this reduction is not pronounced and in most cases persists for only a short time (Table II). In the majority of cases lumbodorsal sympathectomy produces pronounced reduction of the blood pressure, which is still present after a considerable period of time (Tables I and II). DAVID J. INFANTATO, M.D.

MISCELLANEOUS

Gurdjian E. S., Webster, J. E. and Stone, W. E.: The Cerebral Metabolism in Experimental Head Injury. *Wor Med Chic* 944 6 73

An experimental study was conducted to ascertain the effects of head injury on the cerebral oxidative metabolism. Experimental injuries were made on dogs, following which blood specimens were obtained from the femoral artery and the femoral and external jugular veins and were compared with specimens taken previous to the blow. The longitudinal sinus was also exposed, and specimens were taken from this region, following which the brain was further exposed and frozen *in situ* with liquid air. Oxygen levels and carbon-dioxide and oxygen capacity of the blood were determined, as well as the blood level of dextrose and the lactic-acid level in the brain.

The most common observation in this series of experiments was that of increased oxygenization after injury to the head. No significant changes were

noted in the cerebral arteriovenous difference in oxygen. The carbon-dioxide values were about the same as in the control animals. The areas of the cortex showed no macroscopic evidence of contusion, and often appeared entirely normal as regards the chemical constituent studies, even in profoundly injured animals. Areas of cortex which had sustained visible contusion showed marked chemical changes roughly proportional to the degree of local damage, but they did not bear relation to the physiological response. The chemical changes consisted of increase in lactic acid, loss of phosphocreatine and adenosine triphosphate and some increase in inorganic phosphorus.

A study of the effect of oxygen inhalation on brain contusion was conducted. The result would indicate that the administration of oxygen induces no pronounced acceleration of recovery processes, but does seem to produce a trend toward better recovery.

Observations in this study would indicate that the chemical changes in the areas of brain contusion are comparable to the changes observed in cerebral anoxia and in cerebral tissue after death.

Delayed experiments and studies were made after the lapse of several days following injury and improvements were found to have occurred in the oxidative processes in areas of contusion, as evidenced by return toward normal levels of the chemical constituents that were studied.

HOWARD A. BROWN, M.D.

Gurdjian E. S. and Webster J. E.: Acute Physiological Responses in Experimental Head Injury with Special Reference to the Mechanism of Death Soon after Trauma. *Surgery* 944 16 34

In this report the changes in blood pressure, the pulse and respiration, the conscious state, and the reflexes immediately following trauma to the head are considered in detail. The mechanism of death soon after trauma is also analyzed. Dogs morphinized for analgesia were used in the experiments. A variety of preparations were made prior to head injury in different animals: spinal-cord section at the first thoracic level; bilateral adrenalectomy; bilateral vagus-nerve section and carotid-artery ligation and section. Intravenous administration of yohimbine to remove the influence of the sympathetic system, and bilateral supratentorial exposure of the brain. Electroencephalographic studies were made in 9 animals and the findings were analyzed with reference to medullary function.

The acute responses to injury are divisible into 3 types: (1) minimal, (2) moderate, and (3) profound. In moderate and profound injuries there is usually a sudden increase in blood pressure with respiratory loss, unconsciousness, loss of corneal reflexes, and frequent generalized rigidity followed by flaccidity. In moderate injuries the animals survived or died, while in the group with profound injuries they almost always died. Under morphine analgesia the ability to respond to pain was considered an adequate sign of consciousness. Loss of the corneal reflexes repre-

sents a more profound response to injury than unconsciousness.

Evidence of vagal paralysis was common in moderately and severely injured animals but in some there was evidence of vagal stimulation and bradycardia. In the group of animals in which the vagi and carotid arteries were sectioned injury to the head caused responses similar to those seen in the intact animal except that there was no change in the pulse rate. In adrenalectomized animals injury caused the usual rise in blood pressure associated with respiratory failure. It was believed that the increase in blood pressure in this group was not mediated by a humoral factor (adrenalin liberation). In animals with previous spinal-cord section and resulting low blood pressure severe head injury with eventual profound effect was never associated with hypertension. It seems reasonable to assume that if the spinal cord had been intact there would have been the usual acute hypertension following trauma. When an animal was given an amount of 3 ohimbine sufficient to prevent a rise in blood pressure on injection of $\frac{3}{4}$ cc. of adrenalin solution injury to the head was never associated with an increase in blood pressure. These two groups of experiments suggest that the sympathetic nervous system mediates the acute peripheral hypertension which is encountered in head injury.

In several animals with bilateral craniotomy and exposure of the brain a supratentorial bullet wound never caused a pressor effect, although the injury was severe. This indicates that the increase in blood pressure is brought about by medullary stimulation and not by stimulation of the supratentorial cortical

or subcortical centers. In 4 animals the medulla or spinal cord was injured by gunshot. In 2 animals in which the region of the obex was destroyed the pressor effect did not appear. In 2 animals with injury lower down, a marked pressor response appeared in one and an increase in pulse pressure in the other. It is apparent that a dissolution of the vasomotor center itself causes the death of the animal while if the vasomotor center is allowed to remain intact with energies acting upon it from a distance, its first discharge is one of peripheral vasoconstriction with consequent increase in the blood pressure. It is conceivable that in some experiments a depressor mechanism may be the cause of a drop in pressure but paralysis of the vasomotor center itself is usually the cause of circulatory failure and death. The presence of intracranial vasodilatation with peripheral vasoconstriction need not necessarily be construed as evidence of traumatic stimulation of a depressor mechanism since it may happen with any other factor causing peripheral vasoconstriction.

Respirations were affected in a multitude of ways. In general the respiratory response did not appear to be dependent upon vasomotor activity. Respiratory paralysis is a direct result of injury to the respiratory center. The respiratory center or the vasomotor center or both may be affected by trauma.

Electroencephalographic changes did not correlate with medullary involvement. Evidences of medullary paralysis could be obtained without a simultaneous inactivity of the brain waves and conversely in some animals the electrical activity of the brain failed in the presence of respiration and corneal reflexes.

SURGERY OF THE THORAX

TRACHEA, LUNGS, AND PLEURA

Pierson, P. H.: Primary Carcinoma of the Trachea. *J Am Med Ass* 1944, 126: 206

A man of sixty-one who had intermittent bouts of severe cough dyspnea suffocation and moderate hemoptysis for three years was found to have a primary adenocarcinoma of the trachea. An attempt to prove the histogenic origin from an aberrant thyroid by the use of radioactive iodine was unsuccessful. After removal of as much as possible of the tumor through the bronchoscope the remnant was treated with radium applied within the trachea. Two years after treatment there are no subjective or objective evidences of tumor. HOWARD A. MCKENNEY, M.D.

Jones, J. C., and Thompson, W. P.: Arteriovenous Fistula of the Lung. *J Thorac Surg* 1944, 3: 357

In a single white woman, twenty-four years of age, a provisional diagnosis of arteriovenous aneurysm of the right lung was made on the history of cyanosis since birth, the persistent secondary (or symptomatic) polycythemia, the presence of a continuous murmur over the tumor mass in the right lung, clubbing of the fingers, and a normal heart. Later planigraphic studies indicated that there were several masses in the right lung instead of the one tumor mass indicated by the ordinary roentgenogram, that their arterial vascular supply might be separate from those of the upper and lower lobes and that the tumor masses might be made up largely of dilated branches of the pulmonary artery going to the right middle lobe.

After a few months of tentative collapsing of the right lung by means of pneumothorax, the chest was opened through a curved inframammary incision, extending from the third intercostal space anteriorly under the right breast and upward and laterally to the third rib in the midaxilla. There was no semblance of a middle lobe roughly corresponding to where the middle lobe should normally be; there was attached to the anterior and inferior aspects of the upper lobe a reddish-blue pulsating mass the size of a lemon with a paper thin wall. Tapes were passed around what appeared to be the pulmonary artery which was large and dilated, and around the inferior pulmonary vein. No superior pulmonary vein was seen, either at operation or in the specimen after ward. Occlusion of the pulmonary artery suppressed the pulsation in the mass, and occlusion of the inferior pulmonary vein caused the tumor to become larger and more distended. It also caused some superficial varicosities over the surface of the upper lobe to become more prominent. This direct communication between the pulmonary artery and the inferior pulmonary vein was shown, after removal of the lung, on the operatively removed specimen by the

injection of a bismuth medium through the inferior pulmonary vein directly into the pulmonary artery supplying the tumor mass and from here on into the arterial branches supplying the entire lung.

A right total pneumonectomy was done by dissection and individual ligation: first, the pulmonary artery was cut between transfixion sutures, then the inferior pulmonary vein; finally the lung was suspended distal to a clamp applied to the right main bronchus. The right bronchus was closed with right over-end single stainless steel, 35-gauge wire suture, which were tied after the clamp was removed. The mediastinal pleura was closed after thorough irrigation of the stump and of the pleural cavity with saline solution and after 5 gm. of sulfanilamide crystals were sprinkled over the bronchial stump. The ribs were brought together with pericostal sutures and the chest wall was closed in layers without drainage.

Following the operation the cyanosis disappeared within a few hours, the wound healed per primam, and the blood picture returned to normal within a few days. Four months later the patient was well, active, free of dyspnea and cyanosis; the physical findings were completely normal with the exception of clubbed finger ends, and this finding was definitely less in degree. Fluoroscopy showed the right chest to be almost filled with fluid above which was air.

In the discussion ADAMS presented lantern slides showing the photographic appearance, roentgen studies and blood and oxygen studies of a male workman, twenty-four years of age, suffering from repeated attacks of epistaxis, with marked cyanosis, and clubbing of the fingers and toes. Following operation there was an immediate fall in the red-cell count and hemoglobin content and a restoration of oxygen values to approximately normal.

JAMES again discussed his cases, which had been already described in the *British Journal of Surgery*. He believes that many of these lesions are mixed, even by the pathologist, and suggests that we keep hemangiomas in mind as a possible explanation of venous pulmonary bleeding not otherwise explicable.

BROOK tentatively suggests the possibility of closing the fistula by ligation of the pulmonary artery. In this connection, however, JONES, in his closing statement, said that he would rather sacrifice the lung in this case than attempt to dissect out any of the branches or even to leave the lung in and ligate the pulmonary artery. JOHN W. BURNHAM, M.D.

JONES again discussed his cases, which had been already described in the *British Journal of Surgery*. He believes that many of these lesions are missed, even by the pathologist, and suggests that we keep hemangiomas in mind as a possible explanation of serious pulmonary bleeding not otherwise explicable.

BIGGS tentatively suggests the possibility of curing the fistula by ligation of the pulmonary artery. In this connection, however JONES, in his closing statement, said that he would rather sacrifice the lung in this case than attempt to dissect out any of the branches or even to leave the lung in and ligate the pulmonary artery. JOHN W. BARNARD, M.D.

Forbes, G. B.: Chylothorax in Infancy. *J. Pediatr.* St. Louis, 1944, 5: 19.

Chyloous effusion in infancy is so rare that a review of the literature in 1941 contained only 10 cases in infants under one year of age. This report concerns a six weeks-old infant with spontaneous bilateral

chylothorax. Animal experimentation has demonstrated that ingested vitamin A appears quickly in the thoracic duct lymph. In cases of chylothorax, ingested vitamin A is recovered quantitatively from the chyle but carotene given by mouth can be recovered only to the extent of 20 per cent of the amount fed. This study was repeated in this patient with similar results. In addition vitamin D absorption tests were made on this patient and absorption into the chyle was found to be similar to that observed for vitamin A.

The characteristics of the chyle were studied by the author. The infant survived slightly over two months, during which time a total of 5,300 cc. of chyle were removed. The total protein varied from 2.72 to 2.97 gm. per cent the albumin globulin ratio was about 4 to 1. This severe protein loss required intensive therapy consisting of blood plasma and chyle transfusions.

In adults some observations have been recorded on the intravenous administration of chyle. Four of 9 cases were improved in 3 no response was obtained and in 2 cases sudden death occurred, possibly due to an anaphylactic reaction. This patient received a total of 14 chyle infusions ranging from 60 to 100 cc. in volume without reactions. The authors believe that reactions could hardly be due solely to anaphylaxis as chyle normally enters the blood stream. The extensive loss of protein fat, and electrolytes through repeated aspiration of chyle warrants the intravenous use of the fluid removed. No cause for the effusion was found in this patient.

Sampson H. H. and Collis J. L.: Postlobectomy Lobar Collapse. *J Thorac Surg* 1944 13 435

Since lobectomies have been performed for bronchiectasia postoperative collapse of the remaining lobe on the same side has been a perpetual stumbling block in the path of good results. Postoperative collapse may cause increase in mortality prolonged convalescence, or a poor result. Poor results are due to the development of bronchiectasis in the collapsed lobe. One such case is cited by the author.

Secondary collapse has been attributed to such factors as reflex bronchial spasm, swelling of the mucosa due to bronchography, swelling of the stump or the absence of adhesions to aid in expansion of the lobe. Certain bronchoscopic observations made by the authors have led them to advance another theory. At bronchoscopy swelling of the hilum was not noted. The collapse always appeared to be caused by obstruction with sputum and re-expansion of the lobe always occurred when the sputum was removed. Finally when the lower lobe is removed, the upper-lobe bronchus is found to open almost directly upward so that it is parallel to the stump of the lower lobe bronchus. This is due to expansion of the upper lobe in an effort to fill the cavity produced by removal of the upper lobe. In a patient who has an ineffective cough due to pain the

stump easily fills with pus which spills over into the upper lobe. The extent of symptoms depends entirely upon how much pus works into the smaller bronchi.

In practice, bronchoscopy has provided satisfactory treatment. In adults usually one bronchoscopic examination suffices although it may have to be repeated in children. The authors have observed 12 cases of postoperative collapse in 33 cases of lobectomy. All have responded well to bronchoscopy. To date postural drainage has been the only method of prophylaxis that has reduced the incidence of the condition.

THOMAS F THORNTON JR., M.D.

Lewis, R. M.: Muscle-Splitting Thoracoplasty. *J Thorac Surg* 1944 13 437

Head and Wangenstein have described methods for performing thoracoplasty with a relatively low shock factor small wounds and therefore, a smaller potential space for the development of infection. In some far advanced cases of tuberculosis internists and patients have been inclined to refuse operation because of the severity of the classical type of thoracoplasty.

The authors have adopted Head's technique for use in far advanced cases and in those with mixed emphysema. Cosmetic and functional results are improved because of small incisions and because the muscles of the shoulder girdle are not severed. In mixed emphysema the infected field may be avoided until the final stage is performed.

Since 1942 the authors have performed 79 stages upon 31 patients with mixed emphysema or for advanced cavernous disease. Results were uniformly good except in 2 patients with extensive bilateral disease. Modifications of the instruments and technique are discussed.

Paulino, F. and Loureiro, R. L.: Bilateral Thoracoplasty (Thoracoplastia bilateral). *Tr hisp Miguel Pereira*, 1944, ser 1 23

The possibility of bilateral thoracoplasty was first demonstrated experimentally on dogs and monkeys by Kinsella in 1930 and the first successful operation on a human being was performed by Gravesen in 1931. The operation has been performed in a limited number of cases since that time. It is indicated only when bilateral artificial pneumothorax is impossible and only if the patient is in good enough general condition so that survival and benefit from the operation seem probable. The amount of lung tissue involved does not seem to be so important for the success of the operation as the distribution of the cavities. Almost all of both upper lobes may be removed and the patient survive but if cavities are distributed throughout the lungs the operation is impossible.

There is some difference of opinion as to which side should be operated on first, but most surgeons prefer to operate on the side that is in the worst

SURGERY OF THE THORAX

TRACHEA, LUNGS, AND PLEURA

Pierson, P. H.: Primary Carcinoma of the Trachea. *J Am. M. Ass.* 1944, 16, 206

A man of sixty-one who had intermittent bouts of severe cough, dyspnea suffocation, and moderate hemoptysis for three years was found to have a primary adenocarcinoma of the trachea. An attempt to prove the histogenic origin from an aberrant thyroid by the use of radioactive iodine was unsuccessful. After removal of as much as possible of the tumor through the bronchoscope the remnant was treated with radium applied within the trachea. Two years after treatment there are no subjective or objective evidences of tumor. HOWARD A. MCKINNEY, M.D.

Jones, J. C. and Thompson W. P.: Arteriovenous Fistula of the Lung. *J. Thorac. Surg.* 1944, 13, 357

In a single white woman twenty four years of age, a provisional diagnosis of arteriovenous aneurysm of the right lung was made on the history of cyanosis since birth, the persistent secondary (or symptomatic) polycythemia, the presence of a continuous murmur over the tumor mass in the right lung, clubbing of the fingers, and a normal heart. Later planigraphic studies indicated that there were several masses in the right lung instead of the one tumor mass indicated by the ordinary roentgenogram, that their arterial vascular supply might be separate from those of the upper and lower lobes and that the tumor masses might be made up largely of dilated branches of the pulmonary artery going to the right middle lobe.

After a few months of tentative collapsing of the right lung by means of pneumothorax, the chest was opened through a curved inframammary incision, extending from the third intercostal space anteriorly under the right breast and upward and laterally to the third rib in the midaxilla. There was no semblance of a middle lobe roughly corresponding to where the middle lobe should normally be there was attached to the anterior and inferior aspects of the upper lobe a reddish blue pulsating mass the size of a lemon with a paper thin wall. Tapes were passed around what appeared to be the pulmonary artery which was large and dilated, and around the inferior pulmonary vein. No superior pulmonary vein was seen, either at operation or in the specimen after ward. Occlusion of the pulmonary artery suppressed the pulsation in the mass, and occlusion of the inferior pulmonary vein caused the tumor to become larger and more distended. It also caused some superficial varicosities over the surface of the upper lobe to become more prominent. This direct communication between the pulmonary artery and the inferior pulmonary vein was shown after removal of the lung, on the operatively removed specimen by the

injection of a bismuth medium through the inferior pulmonary vein directly into the pulmonary artery supplying the tumor mass and from here on into the arterial branches supplying the entire lung.

A right total pneumonectomy was done by dissection and individual ligation, first, the pulmonary artery was cut between transfixion sutures, then the inferior pulmonary vein finally the lung was suspended distal to a clamp applied to the right main bronchus. The right bronchus was closed with eight over-end single stainless steel, 35-gauge wire sutures, which were tied after the clamp was removed. The mediastinal pleura was closed after thorough irrigation of the stump and of the pleural cavity with saline solution and after 5 gm. of sulfadiazine crystals were sprinkled over the bronchial stump. The ribs were brought together with penicostal sutures and the chest wall was closed in layers without drainage.

Following the operation the cyanosis disappeared within a few hours, the wound healed per primam, and the blood picture returned to normal within a few days. Four months later the patient was well, active, free of dyspnea and cyanosis, the physical findings were completely normal with the exception of clubbed finger ends, and this finding is definitely less in degree. Fluoroscopy showed the right chest to be almost filled with fluid, above which was air.

In the discussion, ADAMS presented lantern slides showing the photographic appearance, roentgen studies and blood and oxygen studies of a milk workman twenty four years of age, suffering from repeated attacks of epistaxis, with marked cyanosis, and clubbing of the fingers and toes. Following operation there was an immediate fall in the red-cell count and hemoglobin content, and a restoration of oxygen values to approximately normal.

JONES again discussed his cases, which had been already described in the *British Journal of Surgery*. He believes that many of these lesions are missed, even by the pathologist, and suggests that we keep hemangiomas in mind as a possible explanation of serious pulmonary bleeding not otherwise explainable.

BROOKER tentatively suggests the possibility of curing the fistula by ligation of the pulmonary artery. In this connection, however, JONES, in his closing statement, said that he would rather sacrifice the lung in this case than attempt to dissect out any of the branches or even to leave the lung in and ligate the pulmonary artery. JOHN W. BUCKMAN, M.D.

Forbes, G. B.: Chylothorax in Infancy. *J. Pediat.* St. Louis, 1944, 5, 91

Chylous effusion in infancy is so rare that a review of the literature in 1941 contained only 10 cases in infants under one year of age. This report concerns a six-weeks-old infant with spontaneous bilateral

chylothorax. Animal experimentation has demonstrated that ingested vitamin A appears quickly in the thoracic duct lymph. In cases of chylothorax, ingested vitamin A is recovered quantitatively from the chyle but carotene given by mouth can be recovered only to the extent of 20 per cent of the amount fed. This study was repeated in this patient with similar results. In addition vitamin D absorption tests were made on this patient and absorption into the chyle was found to be similar to that observed for vitamin A.

The characteristics of the chyle were studied by the author. The infant survived slightly over two months during which time a total of 5,300 cc. of chyle were removed. The total protein varied from 2.72 to 2.97 gm. per cent the albumin globulin ratio was about 4 to 1. This severe protein loss required intensive therapy consisting of blood plasma and chyle transfusions.

In adults some observations have been recorded on the intravenous administration of chyle. Four of 9 cases were improved in 3 no response was obtained and in 2 cases sudden death occurred possibly due to an anaphylactic reaction. This patient received a total of 14 chyle infusions ranging from 60 to 100 cc. in volume without reactions. The authors believe that reactions could hardly be due solely to anaphylaxis as chyle normally enters the blood stream. The extensive loss of protein fat and electrolytes through repeated aspiration of chyle warrants the intravenous use of the fluid removed. No cause for the effusion was found in this patient.

Paulino, F., and Loureiro, R. L.: Bilateral Thoracoplasty (Thoracoplastia bilateral). *Tr. Hosp. Miguel Pereira*, 1944, ser. 1, 23.

The possibility of bilateral thoracoplasty was first demonstrated experimentally on dogs and monkeys by Kinsela in 1930 and the first successful operation on a human being was performed by Gravesen in 1931. The operation has been performed in a limited number of cases since that time. It is indicated only when bilateral artificial pneumothorax is impossible and only if the patient is in good enough general condition so that survival and benefit from the operation seem probable. The amount of lung tissue involved does not seem to be so important for the success of the operation as the distribution of the cavities. Almost all of both upper lobes may be removed and the patient survive but if cavities are distributed throughout the lungs the operation is impossible.

There is some difference of opinion as to which side should be operated on first but most surgeons prefer to operate on the side that is in the worst

condition. The first operation is borne better by the patient and the treatment of the worst side may have a favorable effect on the disease in the other side—it may even render operation on that side unnecessary. At any rate when the lesions on the first side are cured operation on the other side is less dangerous.

German, Argentine and Brazilian surgeons prefer to operate under local anesthesia by infiltration with 0.5 per cent novocain with adrenalin added. The American, French, English and Scandinavian surgeons use general anesthesia with gases. The authors believe that local anesthesia permits closer observation of the respiratory condition during the operation.

It is best to divide the bilateral operation into several stages: the arches of not more than three or four ribs being resected at one time. In the second operation the greatest care should be taken not to reduce the respiratory field too suddenly. Total resection of the first three ribs followed by extrafascial apicolysis by Semb's method should be the first stage in the second thoracoplasty. This extrafascial apicolysis is an indispensable means of furthering collapse of the apex and often reduces the number of ribs that have to be resected. The interval between the two operations must be long enough to permit reossification of the periosteum.

The authors describe 4 cases they have operated upon and illustrate them with roentgenograms. In the first the indication was primary that is both upper lobes were involved at the time of the first operation. In the others it was secondary that is the lesions in the second lung developed after the first operation. In the first operation they resected the whole of the first and second ribs and then after a few minutes observation of the respiration, pulse, and blood pressure, they resected the arcs of the other ribs down to the fifth. Too much of the fifth rib should not be resected. In 2 cases they used Semb's technique with resection to the fourth rib. In both of these cases they had excellent collapse without serious disturbance of the circulation. In 1 case in which the patient's general condition was serious, a resection to the sixth rib had been performed previously. They resected to the fifth rib on the other side in two stages and the results were good. In the only case in which they operated under general anesthesia they were able to resect only to the third rib on account of intense tachypnea. The amount of collapse obtained in this case was insufficient.

In their first case the interval between the operations on the first and second sides was only two weeks, the shortest interval known. In this case there was an intense fibrous reaction and pronounced rigidity of the mediastinum, and the extent of the lesions and the amount of expectoration necessitated the second operation in the shortest possible time. The course in this case was the most favorable of any case they have seen.

AUDREY G. MORGAN, M.D.

HEART AND PERICARDIUM

Taylor, H. A. and McGovern, T.: Angiocardiography: Anatomy of the Heart in Health and Disease. *Radiology* 1944 43 364.

Angiocardiography had its beginning in 1921 when Robb and Weiss started their studies on cardiac physiology and circulation time. At present the method in use is the result of investigations by Forsman, Castellanos and Robb. This type of examination affords a means of determining the size and shape of the heart, the presence or absence of cardiac hypertrophy, chamber enlargement, or both, also the location of the valves and the position of the chambers, the ventricular conus, the pulmonary aorta and its branches, the aorta, and the border forming structures of the cardiac silhouette.

The normal appearance of the heart chambers and the large vessels is described as are the changes observed in size and shape in cardiac patients. The study is based upon observations made on 370 persons, 13 of whom were normal, the remainder had some form of cardiovascular disease. Certain variations from the accepted roentgenographic picture of the normal cardiac silhouette were demonstrated. The middle cardiac segment is formed most often by the left pulmonary artery. Infrequently by the pulmonary aorta, and sometimes by both. The descending aorta may also participate. The conical conus is deeply situated. It is never a border forming structure and is quite removed from the middle cardiac segment.

THOMAS F. THORNTON, JR., M.D.

Proescher, F. and Haumann, F. W.: Abnormal Origin of the Left Coronary Artery with Extensive Cardiac Changes in a Female Child Thirteen Months Old. *J. Pediat.*, St. Louis, 944 35 344.

A case of abnormal origin of the left coronary artery is reported. The patient was a thirteen-month-old female child who had a history of repeated attacks of fever, coughing and wheezing. The patient was admitted to the hospital because of one of these attacks. Physical examination showed flatness of the left lower chest, decreased breath sounds, and crepitant rales. The clinical diagnosis was pneumonia of the left lower lobe of the lung. The child died suddenly fifteen hours after admission.

Autopsy revealed a greatly enlarged heart which occupied the left lower thorax and caused the lower lobe of the lung to be completely atelectatic. The heart was 11.5 by 7.5 cm. and weighed 180 gm. The normal weight of the heart for an infant of this age is about 42 gm. The increased size of the heart was due to left ventricular enlargement. The right coronary artery originated from the right sinus of Valsalva. It was normal in size and had a normal distribution. No vessel originated from the left sinus of Valsalva. Instead the left coronary artery originated from the left pulmonary artery about 1 cm. above the valve. Its orifice was pinpoint in size and

it represented the entire blood supply to the left ventricle as there was no anastomosis between the right and left coronary arteries.

The histological findings were different from the so-called genuine hypertrophy in which there is an increase in the muscle fibers without degenerative changes. In this case there were extensive degenerative changes with replacement by connective tissue and calcification.

The case herein reported brings to 18 the number of infants in whom this anomaly has been reported.

FORESTER D. DOORILL, M.D.

Harrington, S. W.: Chronic Constrictive Pericarditis: Partial Pericardiectomy and Epicardiectomy in 24 Cases. *Ann. Surg.* 1944, 120: 468.

Chronic constrictive pericarditis is the term most generally accepted to designate an inflammatory lesion of the pericardium and epicardium in which fibrous adhesions often associated with deposits of calcium and occasionally pockets of encapsulated fluid form on and between these coverings of the heart, and in which the inflammatory scar contracts around and onto the heart muscle to such a degree that it interferes with the normal diastolic and systolic functions of the heart and causes impairment of the circulation.

The two most common conditions with which constrictive pericarditis is most likely to be confused clinically are cirrhosis of the liver and congestive heart failure from intrinsic cardiac disease. In most instances, however, the subjective symptoms of constrictive pericarditis are sufficiently characteristic so that when they are correlated with the physical and laboratory findings a definite diagnosis can be established.

The development of factors which produce the clinical syndrome of constrictive pericarditis is slow but progressive. The amount of blood entering the heart and being pumped into the circulation by the heart per beat and per minute gradually decreases. This decrease results in low blood and pulse pressure, faint heart sounds, tachycardia, a paradoxical pulse, and auricular fibrillation. The back pressure on the venous circulation results in high venous pressure, dilatation of the veins, enlargement of the liver and transudation of fluid into the tissues of the body, particularly into the abdomen and pleural cavities, as well as into the tissues of the extremities and face.

The number and severity of subjective symptoms increase progressively with the course of the disease, the earliest symptoms are general weakness and fatigue. Dyspnea is noted on exertion and usually is relieved by rest, particularly by lying down. Orthopnea is experienced rarely. Digestive disturbances such as anorexia, epigastric distress, and fullness in the abdomen after meals, usually are not noticed until after the liver is enlarged considerably and probably they can be attributed to hepatic damage for these symptoms seem to be more severe in cases in which the tests of hepatic function reveal a con-

siderable degree of retention of dye. Swelling of the abdomen does not occur early in the course of the disease, however, it may be one of the first symptoms noticed by the patient. When ascites develops it usually becomes progressively more extensive. Edema of the extremities which may extend to the face and neck usually does not occur until after ascites has been present for some time. When venous congestion has advanced to this degree the entire venous system usually is dilated markedly. This dilatation is particularly noticeable in the veins of the cervical region. The effects of this condition cause increasing disability which gradually becomes total disability unless surgical relief is obtained.

The laboratory findings in chronic constrictive pericarditis give valuable aid in establishing a definite diagnosis. The venous pressure is elevated above normal. The circulation time of the blood is increased. The tests of hepatic function indicate a varying degree of hepatic damage which depends to some extent on the duration of the disease.

Röntgenological studies of the heart in cases of constrictive pericarditis usually reveal it to be normal or smaller than normal, occasionally slightly enlarged but never markedly enlarged or segmentally dilated as in congestive heart failure from intrinsic cardiac disease and hypertensive heart disease. The presence of calcareous plaques in the pericardium is noted frequently. This is always suggestive of the possibility of a constricting pericardium but calcium may occur in the pericardium without other findings of constrictive pericarditis.

The preoperative preparation of patients who have been selected for surgical treatment is directed at removing the effects of the circulatory failure from the constriction of the heart and at improving the function of the structures involved.

The intake of fluid should be limited to from 1,200 to 1,500 cc. in twenty-four hours. Patients should receive a diet high in protein and low in salt. Daily administration of vitamins may be of value in improving the general resistance of the patient. When tests of liver function indicate considerable damage vitamin B complex and glucose administered intravenously or by mouth may be helpful in improving the function of the liver.

The body cavities and tissues should be relieved of as much excess fluid as possible. When large amounts of fluid are present in the abdominal and pleural cavities the fluid should be removed by aspiration and periodic use of diuretics should be made to relieve edema of the tissue and keep it at a minimum.

The value of preoperative administration of digoxin is questionable.

The level of blood urea, plasma chlorides and serum protein and the carbon-dioxide-combining power of plasma are determined routinely before operation to see that they are within normal limits as well as for control of the postoperative determinations. The type of the patient's blood is determined and blood of similar type is held available for intrav-

Fig. 1 Sharp dissection of the constricting epicardium (pericardiolysis) and pericardium from the myocardium. Bone cutters were required for resection of the scar because of the thickness of the calcification. Left inset, U shaped precordial incision. Right inset, Approach to the pericardium through the wall of the thorax. Resection of the cartilages and 3 cm. of the third, fourth, fifth, and sixth ribs on the left side (resection proximal half of sternum)

but to shift into another line of cleavage and then separate the intervening bands to avoid myocardial injury

An attempt is always made to free the left ventricle first because better function of this chamber of the heart should be established to provide better disposal of the blood before freeing the right side of the heart. In many instances however the author has separated the greater portion of the right ventricle first without harmful effects.

Opinions differ concerning the amount of pericardial scar that it is necessary to remove as well as the amount of scar to be separated from the heart muscle and from the orifice of the inferior vena cava. The author believes it is advisable to separate as much of the pericardial scar as possible from the ventricles the right auricle and orifice of the inferior vena cava and it is of particular importance to separate the attachment of the right ventricle to the diaphragm. It is of equal importance to separate the apex of the heart, and the author believes that this should be done early in the operation if possible. Separation of the heart muscle from its fixed attachments to the diaphragm is one of the most important considerations in reestablishing the action of the heart. Improvement in the function of the heart

Fig. 2 Resection of, and marginal incisions in, the pericardium and epicardium after separation from the myocardium. Inset a, Beginning resection of the pericardial scar from the anterior and larger surface of the myocardium. b and inset c, After resection of the pericardial scar multiple incisions are made into the cut margin of the remaining epicardium and pericardium to release the heart more fully particularly at the apex. (Courtesy of J. B. Lippincott Co.)

often is noted immediately after the apex and right ventricle have been separated from their fixed attachment to the diaphragm.

After the scar has been separated from the heart muscle the amount of pericardium to be resected depends on the character of the scar and the position and type of fixation of the pleural attachments to the outer wall of the pericardium. The author believes it is advisable to resect as much of the anterior portion of the pericardium as possible without injury to the pleura. By careful dissection the pleural attachments to the pericardium can be separated to approximately the position of the left phrenic nerve and the entire anterior portion of the thickened pericardium extending beneath the sternum is resected. If the attachments of the pleura extend high on the pericardium, as they often do when calcium is present, it may be impossible to resect an adequate amount of pericardium without injury to the pleura. In these cases linear incisions into the remaining cut edges of the pericardium will produce a much wider opening of the pericardium.

The importance of separating and removing sufficient scar to release the heart cannot be overestimated because if an adequate amount is not removed cardiac action will continue to be impaired. This not only will eliminate the possibility of ultimate recovery from the disease but will interfere with the immediate recovery from the operation.

In the course of removal of the pericardial tissue the pulse rate often becomes rapid and irregular because of the external stimulus to the heart muscle. When the pulse becomes irregular it is important to cease the operation temporarily. The utilization of frequent rest periods and applications of sponges moistened with warm physiological solution of sodium chloride will permit the heart to regain or at least partially regain its former rhythm.

The upper half of the wound down to the bed of the cartilage of the fifth rib is closed in two layers. Above the cartilage of the fifth rib the intercostal muscles are sutured to the sternum. The perichondrium of the cartilages of the fifth and sixth ribs is excised completely. From the cartilage of the fifth rib to the lower angle of the wound the subcutaneous tissue and skin only are closed over the heart. Soft rubber tissue drains are placed in the lowermost angle of the wound between the heart and the diaphragm. These drains permit the immediate removal of the serous exudate from the precordial space. The drains are removed from thirty-six to forty-eight hours after operation.

A varying amount of serous exudate always follows removal of the adhesions, even though great care is taken to prevent trauma to the tissues as well as to attain accurate hemostasis. If this fluid is permitted to accumulate in the precordial space it may interfere with the function of the heart which is already laboring under increased stress from the operation. If it is not permitted to drain externally, the fluid may rupture into the pleural space and interfere with respiratory function. When granular deposits of calcium are scattered throughout the pericardium, it is particularly advisable not to have this material drain into the pleural cavity because of the risk of pleural irritation and empyema.

Immediately after operation all patients are placed in oxygen tents. The time during which the administration of oxygen is continued depends on their progress. This is one of the most important aspects of postoperative treatment for the oxygen not only prevents cyanosis but aids in relieving stress on the heart. Other postoperative measures are directed toward removal of body fluids and aiding the function of the heart and liver. These measures are similar to those utilized preoperatively for similar purposes. Limitation of the intake of fluid is important from 1,200 to 1,500 cc. of fluid is administered in twenty-four hours by proctodysis or by mouth as soon as nausea subsides. The intravenous administration of fluids is avoided if possible. In instances in which the urinary output is reduced from 10 to 20 per cent solution of glucose may be administered intravenously. This not only aids the urinary output but may benefit the function of the liver. Vitamin B also is given.

In 24 cases the operative mortality was 25 per cent. Of the 15 patients who recovered from operation 9 are considered "cured" in the sense that subjective symptoms were relieved and the patient was rehabilitated to his former or some other useful

occupation. The improvement of 2 in 24 patients has approximated a cure. In 2 other cases a 3rd operation was recent, improvement has been progressive. Thus 13 of this series of 24 patients ultimately may be considered as cured. Of the remaining 5 patients who recovered from the operation 2 have shown moderate improvement and 3 died. Two of these deaths were due to continuation of the disease and 1 was due to pneumonia.

ESOPHAGUS AND MEDIASTINUM

Haight, C.: Congenital Atresia of the Esophagus with Tracheoesophageal Fistula: Reconstruction of Esophageal Continuity by Primary Anastomosis. *J. N. Surg.* 944, 120-614.

Congenital atresia of the esophagus is found at a level corresponding to the junction of the upper and middle thirds of the esophagus. The upper part of the esophagus ends as a blind pouch in almost all instances. The upper end of the lower esophageal segment usually enters the trachea, thus forming a tracheoesophageal fistula; this occurred in 22 of the 31 patients in the author's series. The condition is incompatible with life as feedings cannot enter the stomach. Furthermore, the feedings and accumulated secretions in the blind upper segment enter into the trachea and death soon results from aspiration pneumonia. Reconstruction of esophageal continuity by a single-stage operation consisting of an extrapleural closure of the tracheoesophageal blind and an anastomosis of the esophageal segments offers the most satisfactory approach to the correction of the anomaly. A primary anastomosis of the upper and lower esophageal segments was done in 10 of the 21 patients for whom an exploration of the anomaly was undertaken. Six, or 37.5 per cent, of the 16 patients are living from seven months to three years and one month after the operation, and the reconstructed esophagus is patent in all instances.

The suspicion of a congenital obstruction of the esophagus is aroused by attacks of choking, dysphagia and cyanosis on attempts to swallow. The actual obstruction of the esophagus can be demonstrated by the inability to pass a catheter into the stomach. To be certain that the obstruction is complete iodized oil is given by mouth under fluoroscopic observation. A dilated blind upper esophageal segment, terminating usually at the level of the second or third dorsal vertebra, is then evident. The presence of a verified complete obstruction of the upper esophagus, the existence of air in the stomach is indicative of a communication between the esophageal segment and the trachea or a tracheoesophageal fistula. The absence of air in the stomach is not necessarily diagnostic of an absence of a tracheoesophageal fistula. The absence of a tracheoesophageal fistula can be determined also by fluoroscopic examination.

The diameter of the upper esophageal segment is always been of ample size to permit an anastomosis but the length may interfere considerably in the

performance of an anastomosis. If the upper segment is short and the lower segment reaches only to the tracheal bifurcation or to a main bronchus the difficulties are augmented. An unusually narrow diameter of the lower segment, a short length of the lower segment (agenesia) and a low position of the tracheoesophageal fistula were the important factors which prevented anastomosis in 6 of 7 patients.

Not bronchoscopy but exploratory operation offers the final criterion regarding the possibility of satisfactory reconstruction of the esophagus in those cases in which the presence of a tracheoesophageal fistula is evident because air is seen in the stomach.

The surgical problem is essentially a threefold one involving (1) the correction of the esophageal obstruction so that aspiration pneumonia will not occur, (2) the ligation of the tracheoesophageal fistula so that gastric contents cannot enter the trachea, and (3) the provision of some means for feeding the infant. Older methods have largely been supplanted by two plans that are now fairly well standardized insofar as surgical principle is concerned.

One plan, the indirect approach, consists of a three-stage procedure: (1) extrapleural ligation of the tracheoesophageal fistula, (2) exteriorization of the upper esophageal segment, and (3) gastrostomy. This indirect plan is essential for the maintenance of life if the anatomic conditions are such that a primary esophageal reconstruction is impossible.

The other plan, a direct approach to the problem advocated by the author, consists of a reconstruction of esophageal continuity by a single-stage extrapleural ligation of the tracheoesophageal fistula and a primary anastomosis of the esophageal segments. Feedings by mouth can be started soon after the operation. If leakage of the anastomosis does not result in an external esophageal fistula or a recurrence of a tracheoesophageal fistula, further operations are avoided.

The technical objection to the plan of primary anastomosis results from the fact that tension is invariably present at the site of the anastomosis. Tension occurs primarily because of the gap that often has to be overcome when the two segments are approximated. The weak tensile strength of the wall of the underdeveloped lower segment is a further technical disadvantage of the direct plan and makes advisable in all cases the complete relaxation that is obtained by general anesthesia, so as to permit the segments to be approximated as readily as possible.

Preoperatively the pulmonary status is carefully determined by physical and roentgenological examinations. If the infant is cyanotic, mucus should be aspirated from the pharynx and oxygen therapy should be started promptly. From the time that a diagnosis has been made, the patient is placed in the prone position with the foot of the bed elevated. This position favors the drainage of oral secretions to the exterior and lessens the tendency of aspiration of pharyngeal secretions. The position is changed to the alternate lateral positions at frequent

Fig. 1. The types of the anomaly that have been encountered at operation in 23 of the 24 cases upon which exploratory operation was performed are illustrated. (One patient died during operation before the nature of the lower segment was determined.) a, The most frequent type of malformation of the esophagus. The upper esophagus ends as a blind pouch. The lower esophagus arises from the trachea at a level that is usually between 0.5 and 1 cm. above the bifurcation of the trachea. Air is present in the stomach which indicates the presence of a tracheoesophageal fistula. This type of anomaly was present in 13 of the 24 patients upon whom a primary exploration of the anomaly was performed. Variations in the location of the fistula were found, and in 2 cases the lower esophagus arose from the right stem bronchus. The anomaly otherwise is the same as in a (5 cases). b, Partial muscular continuity of the two segments. The anomaly otherwise is the same as in a (5 cases). c, The lower segment is greatly contracted for a variable distance below its origin from the trachea and air has not entered the stomach, although a tracheoesophageal fistula was present (2 cases). In a third case, the lower segment was contracted, but air was present in the stomach (not illustrated). d, Atresia of the upper esophagus and agenesis of the lower esophagus. The stomach does not contain air (2 cases). (Courtesy of J. B. Lippincott Co.)

intervals to favor drainage from the upper lobes and thereby lessen the tendency for the development of an atelectasis of the upper lobes. Parenteral fluid consisting of a 3 or 5 per cent solution of dextrose in distilled water is given, preferably by the subcutaneous route. A blood transfusion is ordinarily not given before operation. Its use is deferred until the time of operation. Ascorbic acid and vitamin K are routinely employed as preoperative measures.

Ligation of the tracheoesophageal fistula and anastomosis of the esophageal segments can be performed through either a right or left extrapleural approach. In the 24 patients in the author's series for whom an exploration was carried out, the left extrapleural approach was used in 12 and the right extrapleural approach in 11. In the more recent cases in this series, the right extrapleural approach was used in preference to the left, because of the greater ease in obtaining the exposure of the lower esophageal segment.

The author describes the details of the operative technique using the right and the left approach, respectively.

The percentage of operative recoveries following anastomosis was 37.5. Pneumonia occurred in most of the fatal cases.

JOSEPH K. NADAR, M.D.

Adams, R. and Hoover, W. B.: The Management of Stricture of the Esophagus. *J. Thorac. Surg.* 1944, 3, 383.

The common disease conditions of the esophageal wall with obstruction are (1) cancer of the esophagus (2) esophageal diverticulum, (3) cardiospasm, (4) web (both with and without the Plummer Vinson syndrome) (5) cicatricial stricture secondary to caustic burns (6) cicatricial stricture secondary to peptic ulcer or esophagitis (often associated with peptic ulcer below the esophagus) (7) cicatricial stricture secondary to tuberculous glands of the mediastinum, and (8) congenital developmental anomalies. They have been named in the order of greatest frequency.

The method of treatment of esophageal strictures is dilatation of the narrowed area. A satisfactory result is obtained when the dilatation is sufficient to allow the passage of a regular diet without difficulty. Until this is accomplished the diet may be altered to admit its passage through the narrowed esophagus.

The amount of dilatation or distention that may be obtained in tissues by the application of pressure is to say the least, amazing. In the esophagus may be seen diverticula that have become as large as a grapefruit, and the esophagus may attain a circumference of 10 inches as the result of continued pressure from its fluid content, and the added pressure exerted by the muscles of deglutition.

Passage of the instrument through the esophagus is fraught with danger for trauma to the esophageal wall may result in mediastinitis while perforation or rupture produces mediastinitis except in rare instances. The mediastinitis spreads rapidly and terminates fatally in almost all instances unless radical measures are taken to drain the infection and limit its spread. In such cases the judicious use of the sulfonamides and penicillin must not be overlooked.

The authors review their experiences in the procedure of dilatation of the esophagus for some of the conditions mentioned. They stress particularly the problems they encountered. They have found that it helps a great deal to pass a thread either above or below (in all cases in which this is possible) when

dilatation is attempted, or when the esophagography or bougies are used.

PAUL MICHAEL, M.D.

Ferrari, R. C. and Iturraspe, M. C.: Megaesophagus. Esophagogastrostomy by the Thoracic Route (Megaeosofago. esofagogastronomia por via toracica). *Rev. Acad. argent. cir.* 1944, 18, 509.

Megaesophagus may be treated by dilatation or by operation. The authors describe in detail 7 cases that they operated on and refer to 2 others operated on by colleagues. In all of these successful results were obtained.

The first patient was a farmer forty five years of age who began to have difficulty in swallowing solid foods in 1940 and then for six months the difficulty had extended to swallowing liquids. He had lost 19 kgm. in weight. In January 1943 he was hospitalized with a diagnosis of cancer of the cardia. On operation the cardia was found hard and fibrotic with no palpable glands. A Witzel gastrostomy was performed, but without success and he was sent to the authors for treatment. Roentgen examination showed the dilated esophagus to be filled with retained fluid; it also showed a megacystic mold. This was the second case of this type that the authors have seen. The ninth rib was resected for a length of 18 cm. 3 cm. of the eighth rib were resected at the posterior angle. The pleura was opened and the phrenic nerve was sectioned over the pericardium. A radiating section of the diaphragm was made about 10 cm. from the esophageal opening. The rigid cardia was adherent to the esophageal opening, these adhesions were cut. The esophagus above the cardia was enlarged to about twice its normal size. A lateral anastomosis not involving the cardia was performed between the esophagus and the body of the stomach. Because of the relation of the cardia to the esophageal opening operation by the abdominal route would have been impossible. Recovery was normal and the results were good. The patient can swallow normally and there is no regurgitation. A supplementary operation was performed on the sigmoid sphincter to relieve the stubborn constipation from which he suffered.

The second patient was an Italian fifty-three years of age in whom a Witzel gastrostomy and dilatation were performed before esophagogastrostomy was decided on. The gastrostomy was done under local anesthesia and the final operation under cyclopropane-ether given by tracheal intubation, just like in the first case. Recovery was uneventful, and the functional result was good in this case also.

The discussion was devoted to the relative merits of the thoracic and abdominal routes in this operation, with general agreement that the thoracic route is to be preferred when the surgeon is skilled and the operation is performed in a hospital where all necessary apparatus is available.

In closing, the author said that these were two different operations. In the abdominal operation the esophageal opening is dilated to bring down the esophagus to the stomach, but the pillars of the

diaphragm remain intact and function of the diaphragm is preserved. However in the thoracic operation the diaphragm is paralyzed by section of the phrenic nerve and radiating incisions are made in the diaphragm. These destroy the esophageal opening, and a true hernia of the stomach through the diaphragm is brought about. This cannot have any action on the anastomosis and naturally the results of this operation are better.

AUDREY G. MORGAN M.D.

Harrington S. W. and Moersch, H. J.: Surgical Treatment and Clinical Manifestations of Benign Tumors of the Esophagus, with a Report of 7 Cases. *J Thorac Surg* 1944, 13: 394.

The occurrence of benign tumors of the esophagus is relatively infrequent. Their subjective symptoms and clinical manifestations are often meager which not only delays their clinical recognition but also makes it difficult. These growths are potentially malignant and their treatment is of special interest to the surgeon because extensive operative procedures may be required for their removal.

These benign tumors may be divided into two main groups: the mucosal and the extramucosal tumors. The mucosal tumors are often pedunculated and arise from the submucosa. They usually are fibroidipomas or fibromyxomas and are covered by normal epithelium of the esophagus. The extramucosal, or intramural, tumors arise from the muscle of the wall of the esophagus; they do not involve the mucosa and usually are leiomyomas.

The growth of benign tumors of the esophagus is usually slow and the tumors may attain considerable size without giving rise to subjective symptoms. This is true particularly of the intramural tumors, which rarely produce obstruction of the esophagus unless they attain great size. The common symptoms associated with these growths are dysphagia, substernal pain, regurgitation of food, cough, and dyspnea. The pedunculated tumors are commonly associated with obstructive symptoms and the diagnosis of these growths is often definitely established by regurgitation of the tumor into the mouth, which may be the first subjective symptom. Regurgitation of these growths into the nasopharynx can imperil life because of their blocking the trachea which may result in strangulation.

The roentgenographic and roentgenoscopic examination of the esophagus is of great value in determining the presence of these growths. Esophagoscopy examination is of utmost importance in establishing a definite diagnosis although at times it may be difficult to determine the site of origin as well as the type of growth because it is difficult to obtain a specimen for biopsy through the normal esophageal mucosa. The site of origin of the pedunculated tumors usually can be determined definitely.

The indications for surgical treatment of benign tumors are not as urgent or as imperative as for malignant lesions of the esophagus. They depend somewhat on the patient's general condition the

Fig. 1. Cystic tumor originating from the anterior wall of the middle third of the esophagus, displacing the esophagus to the right (and posteriorly) causing marked compression of the right main bronchus, moderate compression of the left main bronchus, and widening of the coronary angle. Tumor is adherent to the right portion of the pericardium. Upper right insert shows posterolateral incision for transpleural removal of the tumor. Left lower insert shows repair of the esophagus at the site of the tumor.

amount of difficulty the tumor is causing, and the site of the tumor. Inasmuch as these growths may undergo malignant change, surgical treatment should be considered in all cases.

The surgical treatment of these tumors depends on whether the growth is submucous or pedunculated, or on whether it arises from the outer portion of the muscular coat of the esophagus. The pedunculated tumors may be more accessible and amenable to surgical treatment than the intramural tumors. If the pedunculated tumor is small and its origin is high at the introitus it may be removed through the mouth with a snare and cautery. Larger tumors of this type require cervical esophagotomy. These tumors may attain such huge size as to require transthoracic esophagotomy. This approach also may be necessary if the pedicle of the tumor is situated low in the esophagus.

Fig. 2. Resection of the lower fourth of esophagus for removal of a leiomyoma. The stomach was transposed into the thoracic cavity (lower left insert) and the esophagus was anastomosed to the anterior wall of the stomach (lower right insert).

The indications for surgical treatment of intramural tumors are not, as a rule, as urgent as those for pedunculated tumors because intramural tumors do not usually cause obstructive symptoms. The surgical treatment of these tumors often requires a much more extensive operative procedure than is necessary in cases of pedunculated tumors. If the intramural tumors involve only a segment of the wall of the esophagus they may be removed by local excision of the tumor from the wall of the esophagus which is then reconstructed. If the growth involves the entire esophageal wall, its removal will require resection of the esophagus, which entails a greater operative risk.

In 5 of the 7 cases which the authors report esophagectomy was performed in 1 case resection of the esophagus was done and in 1 case the tumor was removed orally with a snare and cautery.

MISCELLANEOUS

D. Abreu, A. L. Litchfield, J. W. and Hodson, C. J.: Intrathoracic Metallic Foreign Bodies. *Lancet* Lond. 1944 547 865.

In a series of 564 severe chest casualties 93 had retained intrathoracic missiles. In 30 cases operative removal was thought necessary and in 49 of these the missile was found and removed. Operative removal of foreign bodies 1 cm. or more in diameter is attempted in view of the risk of infection hemorrhage and structural damage. Operation for the

removal of missiles is delayed until the abnormal physiology due to the injury is overcome. On the other hand too long a delay is not advisable because dense adhesions may form. The foreign body must be accurately localized by x-rays and fluoroscope. If the missile is not easily found at operation portable films should be taken.

A total of 23 patients had missiles removed from the lung in all but 1 the foreign body was a shell fragment. In 5 cases infection was recent, adhesions and palpable tracks leading to the missile were found frequently. Occasionally cavities were present about the metal. In 3 cases calcified nodes near the fragment made identification difficult. In only one case was a lobectomy necessary.

Fourteen cases of pleural foreign bodies were subjected to operation. They offered no special problems when properly localized. Two peripheral and 3 mediastinal fragments were removed. Three missiles were localized in the heart. In 1 of the cases the missiles were not causing symptoms and exposure was not done. In the third case exploration was done but the foreign body was found to be in the interventricular septum and could not be removed. The patient died as did 1 of the patients who had a missile removed from the lung. These were the only operative deaths. THOMAS F. THOMAS, JR., M.D.

Lorena, R.: Radioactivity and Lung Cancer: A Critical Review of Lung Cancer in the Mines of Schneeberg and Joachimsthal. *J. Nat. Cancer Inst.* 344 5 2.

Because of the growing conviction in the United States and abroad that radon gases emitted by rocks inhaled for long periods of time or emitted from radioactive deposits in the lungs will cause cancer of lung in man, the author, Mr. Egro Lorena (a senior biophysicist of the National Cancer Institute of the United States Public Health Service) has presented this review of the literature on pulmonary cancer in the miners of Schneeberg and Joachimsthal. The conviction is based on the fact that primary carcinoma of the lung accounts for 30 per cent of the causes of death of the miners of Schneeberg and Joachimsthal. These mines contain radon, especially where pitch blend is mined. With the use of ever increasing amounts of radon in industries, it is important to know whether radon from radioactive substances will induce pulmonary cancer. Schneeberg is in Germany and Joachimsthal is in Czechoslovakia. The author gives a brief history of the mining activities of these two regions. In addition, he stresses the living, working, and social conditions of the two areas. The article quotes the findings of a great number of men who have studied and obtained material both from the histories and autopsies of individuals in the two regions. Hartung and Hesse reported findings as early as 1879. They found that in 75 per cent of all deaths the cause was lung cancer and that the incidence was greater in miners than in masons or carpenters working in the mines in 1911. Arnsperg reported statistical data showing

that from 1875 to 1912 276 miners had died of cancer of the lung, 64 of tuberculosis 119 of other lung diseases, and 206 from other causes. He was the first to diagnose the cancer as squamous-cell carcinoma. Uhlig in 1921 and Beyreuther in 1924 described isolated cases of lung cancer. Others who have reported include Rostoski and Saupe, Ludwig Lorenser and many others.

The author in reviewing the literature from the many who have reported, has attempted to correlate the histories, the autopsy findings and the living conditions under which these miners work. He then quotes literature giving the radium content of the minerals present, also the radon content of the area in the mines. After this, animal experiments with the animals under conditions similar to those in the mines were made. The animals used included rats, mice and rabbits. The author gives the conditions under which the animals were studied, the amount of exposure to radon, and then the necropsy findings.

In summarizing the findings he states we find that large doses of x or y rays to the lungs (doses in which the total absorbed energy was above 10^4 ergs per cc. of tissue) have not produced lung tumors. Therefore it seems unlikely that the miners of Schneeberg and Joachimsthal exposed daily to the concentration of radon of 3×10^{-3} curies per liter for twenty years should develop lung cancer as the total energy absorbed during that time per cubic centimeter of lung tissue amounts to only approximately 1×10^3 ergs. The energy absorbed in the lungs of the mice of Read and Blottram during 161

days was of the same order of magnitude. No lung lesions were found in these mice. Certain strains of mice have a high susceptibility to spontaneous lung tumors and others a low one but generally the statement of Slye, Holmes, and Wells holds. It seems that man exhibits lung tumors exceptionally infrequently and that mice show an even more exceptional prevalence of tumors of this organ. Evans states "It will be noted from these data that rats and mice are about 40 times as resistive as humans to lesions caused by a rays when all dosages are expressed in erg units. The extrapolation of the results of animal experiments to man must recognize this great difference in susceptibility."

This statement seems not to be justified as far as the effect of radon on lung tissue is concerned.

Therefore, the opinion that radon is the sole cause of the lung cancer of the miners cannot be maintained. The contributing factors in the case of the miners which were already brought up in the different investigations discussed may include the following: pneumoconiosis produced by the dust in the mines; chronic irritation caused by respiratory diseases; arsenic, radioactive substances, and perhaps a hereditary susceptibility. The mines have been operated for hundreds of years. As frequently is the case in Europe the occupation of the father is taken over by the son, the miners live in isolated places and inbreeding often occurs. All these factors may lead to a hereditary susceptibility. However no statistical evidence on this point has ever been collected.

PAUL MERRILL, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Sidel, N. and Wolbarsht, A.: Spontaneous Pneumoperitoneum from an Unknown Cause. *N England J M* 1944, 33: 450.

Pneumoperitoneum may be a spontaneous, diagnostic, or therapeutic condition. When it is encountered except in the form induced for diagnosis, there is usually some lesion in the gastrointestinal tract as the causative factor. Perforation of a viscus is the usual cause. In some cases, the perforation is a slowly developing leak rather than a sudden puncture.

A case of spontaneous pneumoperitoneum, without demonstrable cause and without symptoms is reported. The pneumoperitoneum was discovered accidentally during the course of pneumonia. Subsequently the condition spontaneously disappeared. No gastrointestinal abnormality was found in the history, laboratory tests, or on x-ray investigation. There was x-ray evidence of the marked pneumoperitoneum and of its complete disappearance after a three month interval. SAMUEL KAMEN, M.D.

GASTROINTESTINAL TRACT

Colp, R., Kligenstein, P., Maga, S. and Drucker, L. J.: Subtotal Gastrectomy for Duodenal Ulcer. *Ann. Surg.* 1944, 20: 70.

For six years a definite program has been followed on patients suffering from peptic ulcer. Under this program 173 cases were treated with special emphasis on preoperative management, anesthesia, operative technique, and postoperative care.

Statistics are presented in table form showing the duration of the disease. The important facts in history, analysis of age and sex, choice of operation, pathology, type of gastrointestinal anastomosis and an analysis of pertinent data as to deaths are given.

Gastric analysis showed a uniformly high acid gastric content. Gastroscopic examinations were of no direct value in cases of duodenal ulcer. A high protein diet was used to combat hypoproteinemias. Inhalation anesthesia used during the first three years gave way to continuous spinal anesthesia.

Retrocolic gastrojejunostomy has in turn been replaced by an antecolic isoperistaltic anastomosis. Jejunostomy was used as a complementary or supplementary procedure when indicated. A lower mortality in the second group was attributed in part to spinal anesthesia, the wider use of drainage of the duodenum in the antecolic type of anastomosis, and the frequent use of jejunostomy for alimentation.

The high mortality resulting from early operations on bleeding ulcers will be combated in the future by allowing the patients to convalesce to a nearly normal state before radical surgery is attempted.

RICHARD J. BICK, M.D.

Bremer, J. L.: Diverticula and Duplications of the Intestinal Tract. *Arch. Path., Chic.*, 1944, 31: 17.

The group of anomalies comprising the microgastroschisis, intestinal duplications, and the hirsutic diverticula are divisible into two smaller classes on the basis of embryologic origin. Most of the spherical cysts are derived from true diverticula, which are frequently found projecting from the ventral or antimesenteric surface of the tube in embryos of the eighth or ninth week, and are normally absorbed later. Abnormally they continue to grow. If restricted by the intestinal muscle they bulge within the lumen, but if they pierce the muscle layers outward expansion is unlimited and they may become large cysts attached to the intestine. Their wall is necessarily thicker than the gut wall.

A few of the spherical and most of the tubular structures represent true duplications, which originate by an abnormal persistence of the vacuoles normally present among the mesodermal cells of the solid stage of the intestine. A phenomenon of growth in embryos of the sixth or seventh week. By the confluence of a chain of vacuoles a new channel is formed parallel to the original lumen, and the channel becomes separated from the latter by a union of the intestinal layers between the two. Since the duplication develops within the intestine, the outer wall of the duplicate portion always contains all of the tissue layers of the intestine. The duplicate lumen usually lies between the leaves of the mesentery, but may be entirely separated, with a mesentery derived by the splitting of the original. It may open into the main lumen at one or more places, or become a closed cyst. Theoretically three or more channels are possible, the main lumen and two or more confluent chains of vacuoles.

The duplicate structures assume many forms, some of which are shown and described, and are often associated with other anomalies. In the tubular portions the mucosa tends to resemble that of the parent tube, but in bulbous or cystic portions it changes to the gastric type. Great internal pressure may destroy mucosa of any type.

JOHN E. KIRKPATRICK, M.D.

Kaufman, L. R. and Helman, H. I.: A Case of Spontaneous Gastrojejunal Fistula Eight Years after an Operative Gastrojejunostomy. *Surg.* 1944, 16: 557.

A spontaneous gastrojejunal fistula occurring eight years after an operative gastrojejunostomy is unique. There is no similar case recorded in the literature, nor has one ever been reported by any other physician.

A seventy-year-old white woman was admitted to the Metropolitan Hospital, New York, on April 1, 1943 on account of dysphagia, nausea, and the loss of 10 pounds in three months. She had had dyspepsia

and nausea since youth. A posterior gastroduodenostomy for duodenal ulcer made her comfortable and symptom free for the first time in her life. The patient appeared chronically ill, showed evidence of loss of weight and a marked pallor.

On x-ray examination and fluoroscopy, a normal esophagus was found, the stomach was enlarged and contained a five hour residue, but no gastroduodenal stoma was visualized.

Gastric analyses revealed high total acid up to 75, high free acid up to 48, and high combined acid of 27; there was occult blood in the majority of the specimens.

Gastroscopy revealed a patchy superficial gastritis, an adherent exudate, punctate hemorrhages, atrophic rugae, and a pseudovalve of the stoma with an opening large enough for easy and clear visualization of the jejunum. Many peristaltic waves indicated possible obstruction below the stoma. 2,000 cc of gastric residue were found.

The treatment consisted of gastric lavages, transfusions, and the administration of liver and iron. The hemoglobin increased from 53 to 70 per cent with marked subjective and objective improvement.

Exploratory laparotomy was undertaken after three weeks with the intention of performing a subtotal gastrectomy. The stomach was greatly dilated. Adhesions of the anterior surface to the round ligament and to the parietal peritoneum were easily separated. An anastomosis was visualized at the usual gastroduodenostomy site; there were sharp angulations of proximal and distal jejunal loops. The apparent stoma was located in the transverse mesocolon at the edge of the colon in a large inflammatory mass about 11 by 4 by 7 cm. This mass was dissected from the colon and mesocolon and then from the stomach. The jejunum attached to this mass was resected and an end-to-end anastomosis was made. The gastric wall was inflamed and thickened for a radius of about 2 cm. around the anastomotic site. That portion of the wall was resected. Finger exploration through this opening revealed that distal to it was a wide orifice into what was thought to be the duodenum. However, autopsy showed this orifice to be the original gastroduodenostomy. The anastomosis was the spontaneous inflammatory gastroduodenostomy. The defect of the stomach wall was completely closed and the rent in the mesocolon was sutured. While the stomach was open a Levin tube was guided well into the small intestine.

In the postoperative period oxygen and several transfusions were given. The Levin tube was aspirated at intervals and large quantities of dark brown fluid were removed. Twenty-four hours after operation the patient suddenly went into shock and expired.

At autopsy the gastric mucosa was found to be reddened but not ulcerated. Rugae were not prominent. The pyloric region showed complete obstruction with an area of white scar tissue occluding the opening into the duodenum. An apparently well functioning anastomosis was present. Proximal to

this anastomosis was a sutured defect of the posterior gastric wall. In the descending loop of the jejunum distal to the gastroduodenostomy was an end-to-end anastomosis surrounded by some edema. The mesocolon was scarred and the transverse colon was thickened.

No new gastroduodenostomy was performed since the pylorus and the duodenum were assumed to be patent. Autopsy however showed that there was complete obstruction and that the old gastroduodenostomy was functioning normally.

The most discussed complication following this operation is gastroduodenal ulcer. Fistulas when present, generally are gastroduodenal, jejunojejunal, and gastroduodenocolic. High acid values obviously cause recurrent ulcers, especially when the pylorus is closed. Most gastroduodenal ulcers are clinically similar to peptic ulcers.

The authors quote Alvarez: "Anything that interferes with the passage of duodenal contents over the jejunal mucosa around the stoma is likely to leave this region unprotected from the corrosive effects of gastric juice and, therefore, subject to ulceration. Closure of the pylorus probably interferes with the maintenance of a good downward current in the duodenum, and the absence of food and gastric juice in the duodenum lessens the outflow of the protective bile and pancreatic juice." They also quote Lahey:

"Pyloric obstruction is a predisposing factor for gastroduodenal ulcer since the highly acid gastric contents are dumped into the jejunum and cannot mix with the regurgitant alkaline contents."

Evaluating the pathology in this case the authors assume two hypotheses: (1) the ulcer may have originated in the greater curvature of the stomach as a new ulcer, or (2) the ulcer may have developed as a jejunal ulcer about 8 cm. distal to the original gastroduodenostomy in a location where the impact of the acid chyme would be most likely to produce mucosal ulceration.

As the ulceration progressed through the serosa inflammatory reaction could readily fix a distal segment of the original loop to the greater curvature as well as to the gastroduodenal omentum since it was in close proximity to both. The resulting perforation is then readily understood.

MATTHIAS J. SKIFFERT, M.D.

Dixon C. F. and Benson R. E.: Closure of a Colonic Stoma. Improved Results with Combined Succinylsulfathiazole and Sulfathiazole Therapy *Ann. Surg.* 1944, 120 568.

The oral administration of succinylsulfathiazole and the local application of sulfathiazole to the oper-

ative wound following closure of a colonic stoma have greatly improved the results obtained by the authors. Infection of the operative wound occurred in 84 per cent, and a fecal fistula developed in 30 per cent of a series of 102 cases in which sulfonamide drug was employed, whereas infection of the wounds occurred in only 13 per cent, and a fecal fistula occurred in only 2 per cent of 102 cases in which a combination of succinylsulfathiazole and sulfathiazole was administered. These improvements in the results are in a large part attributable to the new chemotherapeutic agent succinylsulfathiazole, and they indicate in general the usefulness of the drug in the management of surgical diseases of the lower intestinal tract.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Shallow T. A., Eger S. A., and Wagner F. R.: The Conservative Management of Acute Pancreatitis. *Pennsylvania M. J.* 1944, 47 199.

Acute pancreatitis is a disease of middle and old age, equally distributed between the two sexes and rarely occurring in the colored race. The authors observed 12 cases in two years. The cause of the disease is still disputed. The usual view is that it is due to a reflux of infected bile into the pancreatic duct while some investigators believe it is due to reflux of duodenal contents into the pancreatic duct. A third view as to the etiology is a partial obstruction to the outflow of pancreatic secretion due to metaplasia of the epithelium of the branches of the pancreatic duct, and still others believe acute pancreatitis results from a circulatory disturbance of the pancreas.

No one of the current theories adequately explains the mechanism of the production of the disease. There is autodigestion of the pancreas by its own secretion but how the enzymes become activated is not well understood. The liberation of trypsin leads to digestion of the pancreas with necrosis, sometimes followed by suppuration. The tryptic digestion of blood vessels within the gland results in hemorrhage. The liberation of lipase is responsible for an important feature of the disease, namely, fat necrosis. Absorption of the split protein products of the trypsin itself may account for the development of profound shock and death in the very severe cases.

There are two distinct pathological types of the disease: the common form and fortunately the milder acute interstitial pancreatitis or acute pancreas edema. In this condition the gland is grossly enlarged and hard and is surrounded by small areas of fat necrosis localized to the pancreas. Subsequently the inflammation is accompanied by fibrosis. In the less common form, namely the hemorrhagic type, there is blood tinged fluid in the lesser peritoneal cavity. Some of this may find its way into the general peritoneal cavity. The pancreas grossly enlarged, soft and friable and it may be black and

Fig. 1. Closure of colonic stoma. a, Incision in skin encircling the stoma. b, The fascial, muscular and peritoneal layers have been incised and the proximal and distal limbs of the colon are mobilized. The previously encircled layer of skin and subcutaneous tissue is being excised from the wall of the bowel. The edges of the colonic stoma are freshened. (Courtesy of J. B. Lippincott Co.)

Fig. 2. The stoma has been closed transversely to the long axis of the bowel. The completed anastomosis is dropped back inside of the peritoneal cavity and 5 gm. of sulfathiazole are inserted.

gangrenous. The areas of fat necrosis are abundant and are present not only over the pancreas but also are scattered in the mesentery and omentum.

The onset of acute pancreatitis is usually abrupt, often following a hearty meal with severe epigastric pain sometimes radiating through to the back, left flank, or interscapular area. There is nausea and vomiting. In fulminating cases there may be cyanosis, prostration and circulatory collapse. The significant findings are upper abdominal tenderness and rigidity. Tenderness of the left flank is present occasionally. Abdominal distention may be present. Occasionally there may be a bluish discoloration about the umbilicus or in the left flank. Jaundice is not infrequent.

Diagnosis by clinical signs alone is usually impossible but should be confirmed during the acute phase of the disease by a serum-amylase test. This test is practically specific for the lesion and seldom if ever gives a false positive reaction.

The authors believe that if a diagnosis is established clinically operation should be delayed and perhaps it should not be done at all. If the diagnosis is established at the time of operation the most conservative procedure aimed at correcting any obvious contributing factor should be done but no extensive surgery on the pancreas itself.

In the authors' series of 12 cases there were an equal number of edematous and hemorrhagic types of lesions. There was no operative death which they attributed to delayed surgery or very conservative surgery. There was 1 death in the entire series.

EAL O LATIMER M.D.

Brunschwig, A.: The Surgical Treatment of Carcinoma of the Body of the Pancreas. *Ann. S. S.* 1944, 120: 406.

Clinically, cancer of the body of the pancreas is manifested late in the course of the disease. While radical resection of such neoplasms is feasible few patients are subjected to operation early in the evolution of these growths.

Six cases of resection of the body of the pancreas with splenectomy, and 2 cases of total pancreaticotomy with total duodenectomy and splenectomy are recorded. The immediate operative mortality was 50 per cent (4 cases including the 2 pancreaticotomies). One patient with islet-cell carcinoma invading the entire body and later manifesting hepatic metastases, lived three years and eleven months. Of the remaining 3, 2 survived five weeks and five and one-half weeks, respectively. Metastases were present at the time of operation but the patients experienced appreciable amelioration of the severe abdominal pain. The third patient is living, comfortable, and in a fair general condition three months following resection of the body of the pancreas for carcinoma and subtotal gastrectomy for metastases to the stomach. Metastases to the falxiform ligament and umbilicus were also resected.

The technique for resection of the body of the pancreas has been evolved principally as a result of

experience in recent years in excision of pancreatic tissue for hyperinsulinism. The steps in the technique of such resections employed in the cases reported by the author may be summarized as follows:

1. Preferably continuous spinal anesthesia is used.
1. High midline transverse or inverted T incision.

2. Approach to the pancreas by transection of the gastrocolic omentum from the level of the head of the pancreas to the gastrosplenic vessels.

3. Retraction of the stomach upward and of transverse colon downward.

4. At this point, the body of the pancreas may be excised in one of three ways according to the expediency of each situation:

a. Transection of the pancreas at the level of the neck, with resection proceeding distally from the body and tail. Hemostasis is secured by ligation of the branches from the splenic vessels.

b. Division and ligation of the gastrosplenic vessels then transection of the neck of the pancreas and of the splenic artery and vein at this level with excision of the body of the pancreas and spleen en masse, from the neck distally.

c. Division and ligation of the gastrosplenic vessels then elevation of the spleen by grasping it in the right hand; this brings the tail and body of the pancreas forward together with the splenic artery and vein. Transection of the neck of the pancreas and splenic vessels at the level of the superior mesenteric vessels with excision of the body of the pancreas and spleen en masse.

5. Interrupted interlocking silk mattress sutures are placed about 0.5 cm. proximal to the cut edge of the remaining neck of the pancreas. The transected main pancreatic duct, if apparent, is grasped with a hemostat and ligated separately.

6. The transverse mesocolon is repaired except in the region below the pylorus. Here, one or two soft rubber drains are inserted to the site of pancreatic transection.

7. Closure of the abdominal wound.

In some instances of redundant stomach, the gastrophrenic omentum may be transected, the stomach retracted downward and the body of the pancreas excised over the lesser curvature of the stomach.

Total duodenopancreatectomy and splenectomy for practically complete replacement of the pancreas by carcinoma was performed in 2 patients.

ative wound following closure of a colonic stoma have greatly improved the results obtained by its authors. Infection of the operative wound occurred in 84 per cent, and a fecal fistula developed in 30 per cent of a series of 102 cases in which sulfonamide drug was employed, whereas infection of the wounds occurred in only 13 per cent, and a fecal fistula occurred in only 3 per cent of 102 cases in which a combination of succinylsulfathiazole and sulfathiazole was administered. These improvements in the results are in a large part attributable to the new chemotherapeutic agent succinylsulfathiazole, and they indicate in general the usefulness of this drug in the management of surgical diseases of the lower intestinal tract.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Shallow T. A., Eger S. A. and Wagner F. R.: The Conservative Management of Acute Pancreatitis. *Pennsylvania M J* 1944, 47:99

Acute pancreatitis is a disease of middle and old life equally distributed between the two sexes and rarely occurring in the colored race. The authors observed 12 cases in two years. The cause of the disease is still disputed. The usual view is that it is due to a reflux of infected bile into the pancreatic duct, while some investigators believe it is due to a reflux of duodenal contents into the pancreatic duct. A third view as to the etiology is a partial obstruction to the outflow of pancreatic secretion due to metaplasia of the epithellium of the branches of the pancreatic duct, and still others believe acute pancreatitis results from a circulatory disturbance of the pancreas.

No one of the current theories adequately explain the mechanism of the production of the disease. There is autodigestion of the pancreas by its own secretion but how the enzymes become activated is not well understood. The liberation of trypsin leads to digestion of the pancreas with necrosis, sometimes followed by suppuration. The typical digestion of blood vessels within the gland results in hemorrhage. The liberation of lipase is responsible for an important feature of the disease, namely fat necrosis. Absorption of the split protein products of the trypsin itself may account for the development of profound shock and death in the very severe cases.

There are two distinct pathological types of the disease the common form and, fortunately the milder acute interstitial pancreatitis or acute pancreatic edema. In this condition the gland is grossly enlarged and hard and is surrounded by small areas of fat necrosis localized to the pancreas. Subodometer of the inflammation is accompanied by fibrosis. In the less common form namely the hemorrhagic type, there is blood-tinged fluid in the lesser peritoneal cavity. Some of this may find its way into the general peritoneal cavity. The pancreas grossly enlarged, soft, and friable and it may be black and

gangrenous. The areas of fat necrosis are abundant and are present not only over the pancreas but also are scattered in the mesentery and omentum.

The onset of acute pancreatitis is usually abrupt, often following a hearty meal with severe epigastric pain sometimes radiating through to the back left flank, or interscapular area. There is nausea and vomiting. In fulminating cases there may be cyanosis prostration and circulatory collapse. The significant findings are upper abdominal tenderness and rigidity. Tenderness of the left flank is present occasionally. Abdominal distention may be present. Occasionally there may be a bluish discoloration about the umbilicus or in the left flank. Jaundice is not infrequent.

Diagnosis by clinical signs alone is usually impossible but should be confirmed during the acute phase of the disease by a serum amylase test. This test is practically specific for the lesion and seldom if ever gives a false positive reaction.

The authors believe that if a diagnosis is established clinically operation should be delayed and perhaps it should not be done at all. If the diagnosis is established at the time of operation the most conservative procedure aimed at correcting any obvious contributing factor should be done but no extensive surgery on the pancreas itself.

In the authors series of 12 cases there were an equal number of edematous and hemorrhagic types of lesions. There was no operative death which they attributed to delayed surgery or very conservative surgery. There was 1 death in the entire series.

MISCELLANEOUS

Miller, T. G.: Intubation Studies of the Human Small Intestine. A Review of a Ten Year Experience. *Gastroenterology* 1944, 3 131

Presented as the Twentieth Lewis Linn McArthur Lecture of the Frank Billings Foundation, the author gives the results of investigations that have been under way in the Gastrointestinal Clinic at the University of Pennsylvania Hospital, Philadelphia, for the past ten years. They have grown out of a tech-

nique for intubation of the small intestine and, more or less by chance, have led to a procedure of some practical importance in the management of patients with intestinal obstruction.

The technique of intubation permits many investigations of the function of the small intestine including certain physical and chemical facts regarding the fasting contents at various levels and the influence of certain factors on the characteristics of the fasting contents. For preliminary studies the tube was introduced when the subject was in a fasting state.

Fasting specimens obtained by 51 intubations in 30 normal subjects showed that the rate of flow of the contents averaged less than 1 cc. per minute; that the reaction, though usually acid in the duodenum and sometimes so in the jejunum, was essentially neutral throughout the ileum; and that the osmotic pressure, though lower in the duodenum, tended in the jejunum and ileum to be the same as that of the blood plasma (approximately 300 millimoles).

These conditions are altered when solutions are orally administered before the intestinal collections are made because of gastrointestinal motility.

The influence of the ingestion of glucose and food was also studied, as well as the condition in isolated segments.

As glucose enters the gut a normal osmotic pressure is maintained by (1) a displacement of the chloride and bicarbonate ions; (2) an inflow of hypotonic fluid; (3) dispersion of the contents; and (4) absorption of the glucose.

For the preservation of normal conditions above the bowel after the admission of a hypertonic solution, nature employs at least one other procedure in outpouring of mucus that acts as a blanketing layer between the mucosa and the irritant material.

From the beginning the Miller Abbott tube is used in the development of a satisfactory technique for the study of absorption from the intestine.

By special methods the author has been able to make some very preliminary studies on proteolytic digestion, as well as to study the effects of drugs on intestinal functions.

In intestinal obstruction, the chief merit of the two-lumened apparatus lies in the fact that it reaches the point of obstruction and so acts as an internal enterostomy or in the case of an adynamic ileus, as a deflator of the entire bowel. Wengertsen himself admits that his technique has two disadvantages: i. e. the tube does not reach the site of the lesion, and it does not permit use of the bowel above the lesion for purposes of nutrition. Both objections are overcome by intestinal intubation.

In addition to its principal actions—decompressing the distended intestine, aiding in the correction of fluid and electrolyte imbalance, converting emergency cases of obstruction to an elective surgical status, and rendering subsequent operation less hazardous—intestinal intubation also may be an aid in diagnosis. Not infrequently it is capable of localizing the site of an obstructive lesion and by permitting the injection of a thin barium mixture at that point, it may give information as to its nature.

HARRY W. FUNK, M.D.

GYNECOLOGY

UTERUS

Viergliver E. and Pommerenke, W. T.: Measurement of the Cyclic Variations in the Quantity of Cervical Mucus and Its Correlation with the Basal Temperature. *Am J Obst* 1944 48 351

The authors desired to measure accurately the amount of mucus in the cervix at various times in the menstrual cycle by using the basal body temperature shift as the method for fixing the time of ovulation.

The mucus from the cervical canal was withdrawn by aspiration with a glass cannula of known weight. The cannula was then weighed with the mucus and the difference in weight determined the amount of secretion.

Daily vaginal temperatures on arising were taken and recorded.

The study was carried out on 4 subjects in the first subject through six consecutive cycles in the second through three nonconsecutive cycles in the third for one cycle and in the fourth through three consecutive cycles.

A total of 151 observations were made. In the group as a whole, the amount of mucus was increased from about the eighth through the eighteenth day. The individual peaks varied. The usual amount of mucus found preceding or following the days of increased secretion was about 60 mgm. During the periods of increased secretion the amount varied from 200 to 400 mgm. The viscosity of the mucus was usually low from the eighth through the sixteenth day. The maximum secretion of mucus preceded the temperature rise by at least one day.

The authors believe that this may be explanation of the fact that some individuals failed to be come pregnant having had coitus after the temperature rise.

HENRY C. FALK, M.D.

Karnaky A. J. The Use of Diethylstilbestrol to Control Uterine Bleeding. *Southern J* 1944 37 510.

The author attributes normal menstruation and dysfunctional uterine bleeding to fluctuations in the blood estrogenic level. If the estrogenic level is above or below certain limits amenorrhea occurs. On the other hand, if the level is elevated into the bleeding range or if the higher estrogenic levels are lowered into the bleeding range, endometrial bleeding will occur. The degree and rhythm of uterine bleeding will depend upon intrinsic factors which influence the elevation and lowering of the blood estrogenic levels. These factors are dependent upon the metabolism of the granulosa cells.

The author states that all types of dysfunctional bleeding, even if due to fibromyomas as well as amenorrhea may be controlled by the use of large enough doses of stilbestrol.

Four hundred consecutive patients with multiple myomas which were associated with uterine bleeding were given from 50 to 250 mgm. of stilbestrol daily for from ten to sixty days. In all except 8 cases the bleeding stopped.

The method of treatment is as follows:

If the bleeding is severe from 10 to 50 mgm. of stilbestrol are injected into the cervix, or given by mouth every fifteen minutes until the bleeding stops which usually occurs in from two to twenty four hours. Following this from 50 to 100 mgm. are given by mouth each night for a period of from thirty to forty nights. Combined with the stilbestrol thyroid and lipodine are also given.

The author attributes the action of stilbestrol in the control of bleeding to inhibition of the gonadotropic hormones of the pituitary gland plus a diminution in tone of the uterine musculature which is thought to be the result of increased vasodilatation in that area. The increased vasodilatation is followed by an absorption of irritating metabolites with a resultant lessening of the irritation of the smooth muscle.

Among a series of 327 cases 89 per cent of the patients were able to continue the use of large doses of stilbestrol with only a transient period of nausea. The remaining 11 per cent were given elixir of phenobarbital to control a more pronounced gastrointestinal disturbance. In only 0.15 per cent was it necessary to stop stilbestrol because of gastrointestinal symptoms. The administration of large doses of vitamin C (800 mgm. daily) is said to reduce the incidence of nausea. No untoward physical effects were noted from the large doses of stilbestrol.

J. ROBERT WILLSON, M.D.

Ayre, J. E.: A Simple Office Test for the Diagnosis of Uterine Cancer. *Canad M J* 1944 51 17.

In 1941 Papanicolaou and Traut presented an office procedure for the early diagnosis of uterine cancer. This method employed the vaginal-smear technique.

Ayre presents a simple modification of this technique to make the test more rapid and more effective. This modification consists in taking the smear directly from the external os of the cervix. Here the concentration of cancer cells is greater. This was found to be the case in the series of cases studied. Although cancer cells may be found in the vaginal smear the diagnosis should be confirmed by biopsy before operation or radiotherapy. The test is simple and rapid. The biopsy can be taken by any physician and sent to a laboratory for skilled interpretation. Every woman manifesting spotting of blood should have the benefit of a vaginal smear and any positive or doubtful case should have a biopsy without delay.

The technique is presented together with 2 cases illustrating the use of the smear diagnosis.

T. FLOYD BELL, M.D.

ADnexAL AND PERIUTERINE CONDITIONS

MacClure E. Olavo J and Oliveira, C.: Hydatidiform Mole of the Ovary (Mola hidatiforme do ovário) *An. bras. gine* 1944, 8 94.

The interest of the case presented lies in the fact that hydatidiform mole of the ovary is extremely rare. Novak found only 3 cases which had been reported.

The patient was a woman of twenty-one years who was admitted to the hospital with a diagnosis of ruptured ectopic pregnancy on the left side. A week before she had had intense abdominal pain followed by signs of internal hemorrhage. She was operated on immediately after admission. The uterus was found to be congested, the tubes were intact. The left ovary was ruptured and tissue resembling that found in the placenta protruded from the opening. This had been the source of the hemorrhage. A cuneiform resection of the ovary was performed and the wound closed. Uneventful recovery took place and the patient was discharged from the hospital on the eighth day.

Histological examination showed the typical picture of hydatidiform mole localized entirely in the ovary. The later course and the demonstration of negative Aschheim-Zondek tests at the end of three and five months after the operation showed that the condition was benign. Photomicrographs of the findings are given in the original article.

AUDREY G. MORGAN, M.D.

EXTERNAL GENITALIA

Hass, R. L.: Genital Tuberculosis in the Female. *Am. J. Obst.*, 1944, 48 69.

This study is based on a series of 62 cases seen over a period of twenty years. The patients ranged in age from fifteen to sixty-one years. Sixty per cent of the patients were between twenty and forty years of age when admitted.

The chief complaints which brought the patients to the hospital were abdominal pain in 35 per cent of the cases, sinuses or fistulas in 16 per cent, vaginal bleeding in 11.3 per cent and back pain in 11.3 per cent. All other complaints formed less than 5 per cent of the cases.

Although vaginal bleeding was the complaint in only 11.3 per cent of the cases, 58 per cent of the patients in the series complained of some change in the menstrual cycle. This was to be expected since

the endometrium and ovaries were frequently involved.

Sterility occurred fairly frequently in this series. Forty-six patients were married and in the child-bearing age. Twenty of these had not been pregnant making the incidence of "infertility" 43.5 per cent. Forty-eight per cent of the patients had other active foci in addition to the genital lesion.

Eight patients in the series received nonoperative treatment. Four of this group had far advanced generalized tuberculosis and died on an average of three and six tenths months after admission. Three were treated by bed rest, adequate diet, and ultraviolet light, and 2 were alive and well after ten and one years respectively. The third patient in this group died within eight months after admission. One patient with tuberculosis of the cervix refused treatment and is alive twenty years after being seen. She denies any symptoms except amenorrhea at the present time.

Fifty-four patients were treated surgically, the abdominal cavity being opened in 39.

Complete pelvic exenteration with total hysterectomy and bilateral salpingo-oophorectomy was done in 13 cases. In 13 additional cases the same treatment as in the first 13 was given except that the cervix was not removed. In the remaining 23 cases all other operations, including vaginal hysterectomy, removal of cysts, posterior colpotomy and drainage of abscesses, were done.

In this series there were fistulas or wound infections in 24 per cent. In the last 10 patients operated upon since 1936 there have been no wound complications.

The primary operative mortality was 5.5 per cent. Two patients died on the fourth postoperative day, one of pulmonary embolism and the other of peritonitis and intestinal obstruction. A third patient died on the nineteenth day of generalized tuberculosis.

All 62 patients in this series have been carefully followed up. Seventeen (25.8 per cent) are dead after an average of two and three-tenths years. Five died of causes related to pelvic tuberculosis or its extension. The remaining 12 died of causes other than pelvic, the most common being pulmonary and generalized tuberculosis.

Forty-five patients (74.2 per cent) are alive, an average of ten and one half years after their original admittance. Over half of these (57.7 per cent) claim good health. Wound sinuses persist in only 3 patients.

HENRY C. FALK, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Hughes T. D.: Syphilis in Pregnant Women. A Study Based on the Routine Wassermann and Kahn Tests Performed on 28 924 Patients. *Med. J. Australia* 1944, 2: 273

This examination of the blood for syphilis by means of the Wassermann test was commenced by the author in March, 1943 and the figures are carried forward to December 1943. In all 28 924 patients have now been tested and 160 were found to give a positive reaction which was checked in all of the cases. This gives an incidence of 0.55 per cent. As this is the largest series yet published in Australia, it should be a fair indication of the incidence of syphilis in pregnant women attending hospital antenatal departments. In a comparison of the incidence with that of other countries it is difficult to assess its significance because of the mixture of populations and living conditions.

Of the 160 patients diagnosed as syphilitic, the records are available for 134. Potter and Adair state that spirochetes have not been demonstrated in the placenta or in the fetus before the fifth month of gestation; they state also that infection probably does not occur until about this time, that it is not a common cause of early abortion but that it contributes to fetal mortality in the last half of pregnancy.

The following tabulation shows the previous obstetric history of 98 multiparas.

Group A. No miscarriages or other catastrophes 41 (41.83 per cent)

Group B. One or more miscarriages but no other catastrophes 33 (33.6 per cent)

Group C. Prematurity, neonatal death, or still birth 24 (24.5 per cent)

A tabulation of the previous obstetric history of 98 multiparas tends to support the statement that syphilis contributes to fetal mortality in the last half of pregnancy.

Group A. Forty-one or 41.83 per cent, of the patients had no history of miscarriage nor of premature labor, neonatal death, or stillbirth.

Group B. Thirty-three, or 33.6 per cent of the patients had had a previous miscarriage but no other abnormality. In this group it must be realized that the pregnancies ranged from second to the fourteenth.

Group C. In this group the author found that 24, or 24.5 per cent, of the patients had a history of stillbirth, a neonatal death, or a premature birth. A further analysis of group C showed that some patients had experienced more than 1 catastrophe. This was illustrated by the patient who had had 7 pregnancies: 3 premature labors, 2 miscarriages and 2 stillbirths.

The results of the present pregnancies, based on the records of 134 patients are as follows:

One hundred and twenty children were born alive 8 were stillborn and 4 died in the neonatal period there were 2 miscarriages. The combined stillbirths, neonatal deaths and miscarriages numbered 14 or 10.4 per cent.

This figure of a combined stillbirth and neonatal death rate of 10 per cent is in contrast to the previous combined stillbirth and neonatal death rate of 24 per cent. All of the 134 patients, whose latest pregnancies were analyzed, received treatment, the adequacy of which depended upon how early in pregnancy they had reported to the out patient department of the hospital.

The author makes the plea that the Wassermann test be made a part of routine antenatal examination of all patients. CHARLES BARON, M.D.

LABOR AND ITS COMPLICATIONS

MacLennan H. R.: Contracted Pelvis in Child Birth: A Study of Its Morbid Effects on Mother and Child. *J. Obst. Gyn. Brit. Empire* 1944, 51: 293

It was found that contracted pelvis existed chiefly in the industrial centers in Scotland where the standard of living was low. The incidence of contracted pelvis varied with the incidence of rickets. Where rickets existed contracted pelvis also abounded. Where rickets was not present contracted pelvis was virtually absent.

The author reviewed a series of cases from the Glasgow Royal Maternity Hospital which deals with a larger number of contracted pelvises than any other center in Britain. This series of 1 049 cases were admitted to the hospital over a period of two years. They comprised 15 per cent of the total admissions. The series was made up of 560 primigravidae and 489 multiparae. They were divided into 3 groups according to their pelvic measurements: a severely contracted group in which the true conjugate was $3\frac{1}{4}$ inches or less, a moderately contracted group in which the true conjugate was less than $3\frac{1}{4}$ inches but more than $3\frac{3}{4}$ inches, and a slightly contracted group in which the true conjugate was $3\frac{3}{4}$ inches.

The mode of delivery offers evidence as to the dystocia which was present.

One of the most striking features was the dystocia caused by slight cases of contracted pelvis. Only 41 per cent of all primigravidae with slight contraction were able to deliver themselves spontaneously and among the multiparas, only 36 per cent were successful in this respect. The others required operative interference and that interference was of a major type in an unexpectedly large percentage.

Throughout the entire investigation it was noticed repeatedly that the cases of slightly contracted pelvis play a very large part in producing the morbid effects associated with contracted pelvis. This is a

point of considerable significance, in the first place because the slight cases will tend to increase relatively in number as rickets diminishes in severity throughout the country and, in the second place, because the slight cases may escape diagnosis.

It was observed in the incidence of cesarean section (309 cases in all) that the rate rose sharply from 21 per cent in primigravidas to 39 per cent in multiparas.

Thirty-one craniotomies and 53 high-forceps operations were necessary. Many of the patients were admitted to the hospital after an unsuccessful attempt at delivery with the forceps outside. The risks associated with failed forceps are already widely appreciated and the number of such cases occurring in the present series was 36.

The part played by the child in causing dystocia is an important factor. Unless a child is under average weight and not more than 6.5 pounds there is a poor prospect of spontaneous delivery. In studying the averages of weights and the lengths of labor it appeared that there was only a small margin of safety and that a difference in weight of 0.6 of a pound might affect the prognosis adversely. It was also noted with interest that in cases of contracted pelvis of slight degree severe dystocia occurs with a normal 7½-pound baby. However a number of women deliver themselves spontaneously of babies of 7½ pounds and occasionally of over this weight. The main reason for these spontaneous deliveries is that the patient has stronger uterine contractions, a greater endurance than normal, and is temperamentally suited to bear such pain. She may be said to have a satisfactory "labor equation." If this were not the case and if all patients had a similar labor equation, it would be found that the larger the baby the longer the labor. The statistics show no such correlation. One woman may take longer to deliver a 6-pound child than another to deliver an 8-pound child. It may be assumed that an average woman with an average labor cannot deliver an average child if she has a contracted pelvis—be it slight, moderate or severe. For a spontaneous vaginal delivery the child must be below average weight, the mother must have stronger uterine contractions than the average and she must be temperamentally capable of enduring them.

Stillbirth is more than four times more frequent in cases of contracted pelvis than in cases with normal pelvis.

Protracted labor and instrumental delivery were followed often by puerperal sepsis. Twenty-five per cent of all the primigravidas and 18 per cent of all the multiparas were found to have puerperal morbidity.

The maternal mortality rate for the series was 21 per 1,000 (22 in 1,049). In the normal group it was 3 per 1,000. For the purposes of analyses the cases have been divided into 3 groups. The groups may be defined as follows:

GROUP I The patient died immediately after dystocia associated with trauma, shock or hemorrhage.

GROUP II The patient died after dystocia associated with trauma, shock, or hemorrhage followed later by sepsis or postoperative pneumonia.

GROUP III The patient died after dystocia associated with trauma, shock, or hemorrhage, but a concomitant factor such as high blood pressure or pyelonephritis, rendered the patient more vulnerable.

GROUP IV The patient died after dystocia without undue trauma, shock, or hemorrhage, but delivery was followed by postoperative pneumonia, postoperative peritonitis or other postoperative complication.

GROUP V The patient died when measures had been taken to prevent dystocia for example early cesarean section but were followed by shock, peritonitis or other postoperative complications.

GROUP VI The patient died from a condition unassociated with contracted pelvis, but dystocia was a contributory factor.

GROUP VII The patient died from a condition unassociated with contracted pelvis, but contracted pelvis contributed in some way to the fatal issue.

GROUP VIII The patient died from a condition unassociated with contracted pelvis and the contracted pelvis did not in any way affect the fatal issue.

It will be seen that in the first 4 groups death followed dystocia. 67 per cent of the deaths fall into these groups.

In the 5th group death occurred following measures taken to prevent dystocia. 23 per cent of the deaths occur in this group.

In the 6th, 7th and 8th groups contracted pelvis is either a contributory or only an incidental factor. These latter groups account for only 10 per cent.

It is important to consider what steps may be taken to improve the present position. The first and ultimate remedy must clearly be the prevention of rickets even in the mildest forms, for the investigation has shown that the slight cases of pelvic contraction give rise to as great difficulty today as do the severe ones. It is already well recognized that dietetic and social factors are primarily responsible for the production of rickets. The fact however that methods of preventing rickets are already well known and that rickets in its grosser forms is something so rarely to-day leads sometimes to an attitude of mind which supposes that the danger of rickets has ceased to exist whereas in fact, the condition is still prevalent in minor degrees. By being minor and "masked" it is all the more dangerous to female children when they reach the childbearing age and are discovered to be suffering from contracted pelvis. It will be readily admitted that the first line of defense against rickets is the care of the child by a healthy and intelligent mother. The value of the antenatal clinic cannot be overestimated from the viewpoint of the mother's general health. The nourishment of the mother during pregnancy and particularly during lactation may be of primary importance in producing or preventing rickets in the offspring.

There are two main defects in the system. The first is nonattendance. The second defect is failure on the part of the mother to utilize adequately the advice given at the clinic or by her doctor. This may be through lack of education or facilities.

The investigation has attempted to show the advantage that would be gained if every case of contracted pelvis were recognized before labor so that provision for skilled treatment could be made in ample time. The earlier recognition of contracted pelvis implies an improvement in the general level of antenatal pelvimetry.

In the hospital the greatest care is required for accurate estimation of the degree of deformity present. Today this can be done most satisfactorily by means of roentgenological pelvimetry. It is, of course essential that one of the well proved methods should be chosen.

In a trial of labor when the size of the pelvis has already been ascertained it is essential for the obstetrician to acquaint himself with the quality, duration and frequency of the uterine contractions. Not only is the quality of uterine contractions of importance but the patient's capacity to endure strong contractions must also be borne in mind.

The purpose of this work was to draw attention to the rachitic pelvis which causes such disaster to the mother and her child. The remedies are in our hands. We must apply them.

CHARLES BARON M.D.

Tollefson, D. G. Methergine (Synthetic Lysergic-Acid Derivative) A New Oxytocic. Preliminary Report. *West J Surg* 1944 52 383

Methergine is d-lysergic acid d-1-hydroxybutylamide a synthetic ergonovine derivative. The availability of methergine may come to represent an outstanding achievement in ergot chemistry and therapy because of the scarcity of adequate quantities of rich crude ergot of rye high in alkaloidal content.

Hemorrhage next to infection is the most common cause of maternal mortality. The hemorrhage occurring in the third stage of labor is due to failure of the uterus to contract, therefore any medication which insures a rapid and prolonged effect is a valuable adjunct to our therapeutic armament.

Since the use of analgesia is almost routine in modern obstetrics and the relaxing effect of these pain relieving drugs cannot be denied, it seemed that the use of medication in a group of pregnant patients would be the best possible test.

To 200 patients who received as a minimum 6 gr. of nembutal and 1/100 gr. of scopolamine (many had additional medication and almost all had cyclopropane for delivery) 1 cc. of methergine containing 0.2 mgm. of lysergic acid d-1-hydroxybutylamide was given intravenously as soon as separation of the placenta was in progress. The usual signs of separation are not always reliable but in this series the placenta was palpable in the cervical opening. The action of the oxytocic was rapid and was apparent

on an average in forty-eight seconds. As soon as this contraction was palpated simple expression was practiced and the placenta was expelled almost immediately. Blood loss in this series averaged 98 cc.

During the puerperium, methergine was given in doses of 3 tablets daily for several days and involution of the uterus proceeded satisfactorily. In this series the lochia was noticeably reduced.

The last 200 patients delivered remained in the hospital on an average of eight and four tenths days. Nine patients have been readmitted to the hospital because of excessive flow. Two patients had been given methergine, and both were curetted—one on the twenty-second day, the other on the seventeenth day. Normal endometrium was removed in one, in the other a small placenta fragment was removed.

In 12 patients not included in this series this drug was given before the separation was completed and a powerful contraction of the cervix caused an incarceration of the after birth. In 2 two hours elapsed before the contraction relaxed although bleeding was not excessive.

The author's experience would suggest that the administration of methergine should be delayed until separation is complete or at least in progress.

NEWBORN

Erickson, C. A.: Rubella Early in Pregnancy Causing Congenital Malformations of the Eyes and Heart. *J. Pediat.*, St. Louis, 1944, 25 381

Three series of cases were reported from Australia in which virus infections, particularly rubella occurring in early pregnancy seemed to be related to congenital defects. The author reviews these and reports an additional 11 cases.

The duration of pregnancy at the onset of the rubella varied from two to ten weeks. Cataracts, microphthalmia or corneal opacity was present in all 11 babies.

Most of the babies were small and experienced feeding difficulties. Congenital heart defects were present in 9 of them. Two were considered mentally retarded and 1 had a severe anemia resembling erythroblastosis.

Important developmental changes occur in early pregnancy, which coincided with the occurrence of rubella. Increased observation may incriminate other virus infections as the cause of congenital anomalies.

The author states that in view of the constant occurrence of serious congenital anomalies in association with rubella in early pregnancy we should seriously consider (1) deliberate exposure at an opportune time in childhood (2) the use of convalescent serum on susceptible pregnant women particularly if they have been exposed (3) therapeutic abortion if rubella occurs during the first two months of pregnancy and (4) research on animals with other types of virus infection.

JAMES F. DONNELLY M.D.

Evans, M. W.: Congenital Dental Defects in Infants Subsequent to Maternal Rubella during Pregnancy. *Med. J. Australia*, 1944, 35

Maternal rubella occurring in early pregnancy is associated with a high frequency of congenital anomalies among which dental defects have been noted. Dental examinations were conducted on infants born of mothers having had rubella in early pregnancy.

Of the 34 babies examined 23 showed congenital dental anomalies major in nature in 18 cases. All but 2 had other congenital defects. The most severe defects were present when the maternal infection occurred between the sixth and ninth week of pregnancy which is considered to be the critical period of dental development. The main abnormalities noted were retardation of eruption, enamel hypoplasia and dental caries.

JAMES F. DONNELLY, M.D.

Swan, C.: A Study of 2 Infants Dying From Congenital Defects Following Maternal Rubella in the Early Stages of Pregnancy. *J. Path. Bact. Lond.* 1944, 56: 189.

Gregg first recorded the fact that mothers who contracted rubella in early pregnancy gave birth to infants suffering from congenital cataract often associated with congenital heart disease.

This report presents the observations made during autopsy on 3 of these infants.

All were small, thin and undernourished. The anterior fontanelle was larger than normal in 2.

Ocular abnormalities were noted in 3 infants. Unilateral microphthalmia was present in one infant, the other eye being cataractous; the other infant had bilateral cataracts. Microscopically the nuclear portion of the lens showed massive necrosis. There was disintegration of the cortical lens fibers which had been replaced by vacuoles. The fibers still living showed swelling, irregular staining and granularity and vacuolation of the cytoplasm. The lens fibers were swollen and pale. Very little reparative effect was seen.

A variable enlargement of the heart was found. The ductus arteriosus was widely patent in all 3 cases, as was the foramen ovale. In 1 there was in addition a defect of the interventricular septum. Microscopically the ductus arteriosus was noted to have a larger lumen and thinner wall than in the controls. The internal elastic lamina was either ill defined or absent.

Atelectasis and bronchopneumonia were present in the lungs of all 3 cases. Minute foci of degeneration and necrosis were found in 1.

In the kidney occasional glomeruli were small and showed partial or complete replacement of their capillaries by hyalinized fibrous tissue. Some proliferation of the parietal layer of Bowman's capsule was seen but it differed from the crescentic type of glomerulonephritis.

No lesions were noted in other viscera.

Considerable evidence seems to indicate the virus of rubella as the cause of these congenital abnormalities.

The mechanism is not clear but it appears that the virus affects the blood vessels primarily.

MISCELLANEOUS

Grossmann, L. L.: The Diagnostic and Therapeutic Use of Prostaglandin: Its Effect upon Pregnancy or Delayed Menstruation. *Wad. J.* 5: 1944 5: 443.

The rationale and use of prostaglandin in diagnosing pregnancy and/or treating delayed menstruation are described.

The drug was employed in diagnosing accurately or in treating effectively 100 cases of delayed menstruation due to pregnancy or some other cause. Patients were injected with 1 cc. of prostaglandin methylsulfate (1:1,000) on three successive days unless bleeding ensued after the first or second injection. In 46 instances when bleeding did not result, pregnancy was correctly assumed to be present. In 4 of these 46 cases the Aschheim-Zondek test was negative at the time of the injections; these patients were later proved to be pregnant. In no case did bleeding occur in the presence of pregnancy so far as could be determined clinically.

The test is inexpensive, simple to apply and does not require laboratory assistance for verification. Apparently uterine bleeding will almost invariably result in cases of amenorrhea not due to pregnancy or endocrine deficiencies, the menopause (3 cases) or gross pelvic disease. The onset of bleeding is due presumably to the production of uterine hyperemia by the drug.

DAVID G. MORROW, M.D.

Pracott, F., and Bazzan, M.: Inhibition of Lactation by Hexoestrol Dipropionate. *Brit. M. J.* 1944 438.

The authors briefly discuss the physiology of lactation and describe the rationale for using estrogen for the inhibition of lactation. Estrogens probably depress the activity of the anterior lobe of the pituitary gland. The absence of suckling plus estrogen administration produces the most satisfactory inhibition of lactation.

A review of the various methods currently used for inhibiting lactation, and their results, includes such substances as stilbestrol, hexoestrol, dienoestrol, trichlorethylene, testosterone propionate, and methyl testosterone. These substances are usually given by mouth over periods varying from three to ten days.

The authors point out that castration of the estrogens retards their rate of absorption and diminution and thus prolongs their action in the body. Hexoestrol dipropionate was found to be not as effective by mouth, but the duration of action was much as long. It was therefore decided to try its effect in the suppression of lactation.

Two groups of patients were used: 23 were given hexoestrol dipropionate by mouth and 44 were given this substance in oil intramuscularly. All patients treated were those in whom it was necessary to inhibit

bit lactation because of stillbirth abortion neonatal death or cracked nipples. The oral dose of hex estrol dipropionate used was between 10 and 20 mgm three times daily for three days. The dose by injection was 12.5 mgm. in one injection within the first three days after delivery.

The results of these treatments revealed that a single intramuscular injection of 12.5 mgm of hex estrol dipropionate inhibited lactation in 66 per cent of the 44 mothers within the first three days of delivery. Lactation did not occur and there were no signs of breast engorgement or discomfort. In the remaining 34 per cent repeated injections brought relief to all but 2 per cent. 18 per cent required treatment for more than three days after delivery.

A further course of injections was necessary to suppress "secondary filling" in only 7 per cent of the cases. This compares well with percentages ranging from 25 to 45 for stilbestrol as reported in the reviewed literature.

Hexoestrol dipropionate given by mouth was not so satisfactory as when given by injection.

HARRY FIELDS, M.D.

Argenti P: Childbirth in the Greek Island of Chios in the Sixth Century B.C. *J Obst. Gyn. Brit. Empire* 1944, 51: 344.

Two Greek terracottas small votive offerings are in the Museum at Nicosia in Cyprus. The one represents a woman being delivered of child in an upright seated position, she is held from the back by another woman, who has her hands clasped round her belly and who is probably pressing the infant downwards exactly as described in "The Expert Midwife" of 1637 and in Sonnini's description written in 1780 in front, and facing her in a kneeling posture, is the midwife with her arms outstretched to receive the after birth. The second terracotta is more coarsely modeled and may be older; it represents a similar scene except that the seat on which the pregnant woman is reclining is missing and from the angle of the thigh it would appear to have been higher; also there is no trace of a third woman supporting from the back the woman in labor.

These terracottas establish the fact that in classical times women were delivered in an upright perpendicular position; also that then in all probability some kind of special labor-stool was in use.

From what Sonnini writes, we may definitely deduce that at the close of the eighteenth century the labor-chair was no longer in use in France. The labor-chair which was in use in Chios until about 1914 was higher than the tripod represented by Sonnini, and had a back in accordance with the ideas expressed in "The Expert Midwife" but instead of being concave to fit the curvature of the body it is straight like an ordinary chair.

In Chios doctors took over, so to speak, from midwives as late as about 1914. The following information was given by an old woman who had practiced midwifery on the island for many years before her retirement.

As there were no means of communication in Chios except a few inferior roads the midwife went on her round on muleback, generally accompanied by an assistant, who for choice would be her daughter and successor-elect to her practice on one side of the mule was strapped the labor-chair which folded up having heavy hinges behind the seat and at the junctures of the arms and back. For padding shaped cushions were tied to the different parts of the chair. The pregnant woman was seated in the chair and in order to bring on the child, was jolted up and down from the back by the assistant who held her under the arms. If the woman was heavy the jolting was carried out by one of the women members of the family who helped by holding the woman under the left arm with her right hand and the midwife's assistant doing likewise on the right side with her left hand thus leaving the right arm of the more experienced assistant free for pressing down the belly of the expectant mother. The midwife's position was exactly similar to that of the one represented in the terracottas dating from 600 B.C. The midwife's after treatment continued for eight days after which the mother was considered to be in condition to resume her normal life.

CHARLES BARON, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Zide, H. A. Renal Complications of Sulfonamide Administration: Report of Reactions from Sulfathiazole and Sulfadiazine. *J Urol* Balt., 944, 58 75

The case histories of 10 patients with 11 renal reactions to sulfonamides 1 to sulfathiazole and 10 to sulfadiazine are analyzed.

The minimum dosage before renal symptoms occurred was 7 gm. of sodium sulfadiazine given intravenously.

The minimum time before onset of the renal symptoms was twenty four hours.

Two delayed reactions occurred one six days and the other twelve days after sulfadiazine was discontinued.

The urinary reaction to litmus paper during the renal complications was acid in 8 instances and undetermined in 2, and alkaline in 1 instance.

The blood sulfadiazine level ranged from 23 mgm per cent to 4 mgm. per cent at or about the time of reaction being over 8 mgm. per cent in most cases.

The treatment of this series of cases consisted of conservative means in all, with an unsuccessful attempt at manipulative treatment in 1 case which later responded to conservative treatment.

The end-results were cures of the original conditions and renal complications in all cases.

The prophylaxis and treatment of renal complications of sulfonamide administration are discussed.
JOHN A. LOFF, M.D.

Baratz, L. H.: Renal Hydrocele; Subcapsular Renal Extravasation. *J Urol* Balt., 944, 5 84.

In a renal hydrocele the true capsule of the kidney is separated by urine so that the kidney is situated at the base of the sac. The etiology is dependent upon renal trauma and the following associated factors: (1) trauma or perforation which opens the pelvis or calyx, (2) a maintenance of the opening beyond the healing period, (3) an acquired or pre-existing hydronephrosis, and (4) slow extravasation beneath a normal uninjured capsule.

Gross pathology shows the capsule of the renal hydrocele to be composed of Gerota's fascia, perinephric fat and fascia, and renal capsule all compressed and thickened into a shining membrane. On microscopic examination the inner surface shows a single layer of flat, or cuboidal cells on a loose, fibrous connective tissue. The deeper portions of the membrane show elastic fibers and lobules of adipose tissue separated by connective-tissue septa containing engorged capillaries. The sac is of variable proportion and the kidney surface is often characterized by multiple cortical abscesses with areas of coagulation necrosis and involvement of the tubules with eventual autonephrectomy.

The author reports 8 cases from the American literature, all of which demonstrated a urinary extravasation beneath the true renal capsule. It is mentioned that other cases reviewed both from the American and foreign literature did not demonstrate that the sac lining was composed of true renal capsule.

The patient initially presents abdominal discomfort associated with an ever increasing abdominal tumor. The subjective findings of nausea, vomiting and pain appear later along with findings of tachycardia and a low grade temperature, in addition to an elevated total white blood-cell count, secondary anemia, drowsiness and marked weakness. The urine findings are limited to possibly a few white cells and seldom hematuria.

Cystoscopic examination may reveal no drainage of urine from the affected side, and pyelography may be vague because of the mass in the area, which in turn causes ureteral displacement or compression, or both. Furthermore barium in the stomach discloses a roentgen outline of that organ which is forced laterally and anteriorly. The diagnosis of renal hydrocele is established at operation, but with a history of trauma and the discovery of a displaced and compressed ureter the diagnosis of renal hydrocele should be suggested.

The case of a patient thirty-seven years of age, who was found to have a left renal hydrocele after child delivery is reported. The sac was drained and nephrectomy avoided. This patient was treated by aspiration of the urine and the maintenance of free drainage through the operative incision. On the forty-fourth postoperative day no further evidence of urinary drainage was evident from the low wound the patient was discharged from the hospital on her forty-sixth postoperative day. An intravenous pyelogram a month later revealed normal calyceal and pelvic morphology. The case is well illustrated by pyelographic reproductions, and stomach displacement is clearly demonstrated in another reproduction.

In the treatment of renal hydrocele, early operation is imperative. In the absence of extreme toxemia a repair of the calyceal fistula may be feasible. However in extreme toxemia, drainage of the cyst should be performed followed by nephrectomy at a later date. If the suppurative process subsides, subsequent nephrectomy may be avoided, as it is in the case reported by the author.

ROBERT LACK, JR. M.D.

Semana, J. H. Nephrectomy for Hypertension in a Two-and-One-Half Year-Old Child with Apparent Cure for Three Years. *Bull. Johns Hopkins Hosp* 1944, 75 84.

Some difficulty remains in selecting those patients with hypertension who can be permanently relieved

by nephrectomy. The solution of this problem will be aided by reports of cases carefully studied before and after operation. In the case described the blood pressure changed from a maximum preoperative level of 200/134 to one of 98/62 at the time of the last visit, three years after operation. The microscopic diagnosis of the lesion in the extirpated kidney was chronic pyelonephritis. However marked perirenal fibrosis a cause of experimentally produced hypertension in dogs seemed the most important etiological factor in this case. A retroperitoneal teratoma had been removed four months previously from the region of the kidney. Symptoms began following this operation.

The decision to explore the left kidney was based on several considerations. On three occasions intravenous injections of diodrast outlined only the right upper urinary tract. Failure to demonstrate secretion of radiopaque material with x rays in any one instance is not pathognomonic of renal disease but when one of two kidneys is persistently unable to secrete the material in sufficient concentration to cast a shadow, it signifies little or no function on the blank side. Also in this case the left kidney secreted less phenolsulfonphthalein than the right.

At operation there was a large amount of dense scar tissue around the kidney. No constriction of either the renal artery or its extrarenal branches was evident. However in view of the poor prognosis and of the findings suggesting renal disease on the left side nephrectomy was carried out. The elimination of hypertension in this patient for a period of three years shows the relationship between the hypertension and the lesion in the left kidney.

While there was intimal thickening of some of the intrarenal arterioles it seems probable that the perirenal fibrosis may have been a factor in producing this patient's hypertension and that previous removal of the teratoma from the retroperitoneal space resulted in the development of this fibrosis.

JOHN A. LOFF, M.D.

Scott, W. W.: Supernumerary Ureter with Extravascular Orifice. *J. Urol.* Balt. 1944 53: 126

Four cases of supernumerary ureter with extravascular orifice are reported. All occurred in females. These cases bring the total recorded in the literature to more than 300 and according to Thom the actual incidence in the female is twice that in the male although the apparent incidence is much less since the condition is asymptomatic because the ureter empties into the prostatic urethra, seminal vesicle vas deferens or ejaculatory duct.

The embryological explanation for aberrant ureteral insertion in the male is not disputed but in the female, when the ureteral orifice is vaginal, there is disagreement since the vagina is of müllerian-duct derivation. However Winterton's work is mentioned this assumes an initial ureteral insertion with vaginal ectopia in the event of a break through the wall separating the wolffian and müllerian systems. Furthermore, it is reiterated that the most

cephalad pelvis is always drained by the ureter having the more caudad insertion.

Regular normal micturition despite incontinence in the female characterizes the condition. The incontinence though both diurnal and nocturnal, may be either or it may be intermittent. Mulholland collected 9 cases without incontinence.

The history of normal regular micturition and continuous incontinence permits a presumptive diagnosis of extravascular ureter. The diagnosis is confirmed by intravenous and retrograde pyelography.

The finding of a large kidney with the upper portion showing no collecting system strongly suggests duplication. Therefore, these findings and a single ureteral opening on the side, together with the characteristic history of incontinence in a female supply sufficient evidence to warrant surgical exploration of the abnormal kidney.

The authors advise heminephrectomy with partial ureterectomy in the treatment of supernumerary ureter and extravascular orifice. The following résumé of the 4 cases is presented.

Case 1: A girl was first seen at the age of five years for a then diagnosed chronic pyelitis and two years later by retrograde pyelography was found to have a supernumerary ureter with an extravascular orifice. A heminephrectomy and partial ureterectomy were done and the patient has enjoyed good health during the nine years postoperatively.

Case 2: A twenty-one-year-old female was subjected to a right heminephrectomy following the diagnosis of supernumerary ureter with an extravascular orifice which was located in the region of Skene's duct on the right. The postoperative course has been uneventful.

Case 3: A twenty-three-year-old female with urine seepage from birth demonstrated by means of intravenous pyelography a collecting system in the superior segment of the large left kidney shadow and on this finding the diagnosis of supernumerary ureter with an extravascular orifice was made. The left heminephrectomy showed little dilatation of the supernumerary segment which explained the adequate dye concentration in the intravenous urograms.

Case 4: A girl of fourteen years showed no evident extravascular ureteral orifice but pyelography showed on the left side a large renal shadow with no collecting system for its upper portion. On this finding a left renal exploration was done and a double kidney and ureter were found. The upper ureter and pelvis were dilated. A heminephrectomy was done.

ROBERT LUCH, JR., M.D.

Goldstein, A. E. and Berman, E. F.: Ureterocutaneous Transplantation. A New Procedure. *J. Urol.* Balt. 1944 53: 324.

Although ureterointestinal anastomosis is a very satisfactory method of diversion of the urinary stream, ureterocutaneous transplantation is indicated in a considerable proportion of the cases requiring diversion of the urine. The conventional

but still attached to bladder

Fig. 4. Anatomical relationship.

operation of ureterocutaneous transplantation has had several disadvantages: namely, perireteral infection with abscess and slough of the ureter; retraction of the ureteral stump; stricture or kinking of the ureter; and insufficient length of the ureteral stump to permit of a properly adjusted apparatus.

A new technique of ureterocutaneous transplantation, the fundamental principle of which is the establishment of the "right of domicile" of the ureter on the anterior abdominal wall, is described. At the first stage of the operation the ureter is approached through a Gibson incision extraperitoneally and is bluntly dissected free down to the bladder. A loop of silk is passed around the ureter and the ends are led out to the skin to assist in locating the ureter at its junction with the bladder at the second stage. The internal and external oblique muscles and fascia are united behind the ureter, which makes it a subcutaneous structure. No sutures are placed in the ureter and the ureter is not opened at the first operation. It is desirable but not always possible to introduce an indwelling ureteral catheter through the cystoscope preoperatively in order to provide drainage and prevent kinking of the ureter during the three to seven days between the two stages. During this interval the ureter is stretched somewhat and new sources of blood supply are obtained. Leaving the apex of the ureter in the subcutaneous tissues

also provides for observation of its blood supply at frequent intervals.

At the second stage the distal end of the ureter is ligated and phenolized and the proximal portion is brought out as a 3 to 5 cm. ureteral stump. A urethral or Foley catheter is inserted into the pelvis of the kidney to provide drainage. Cystectomy may be performed at the second stage of the operation. The authors consider the use of a cupping device theoretically more suitable than an indwelling catheter but they have been temporarily unable to obtain satisfactory appliances.

Three cases are reported in which this method has been employed. Two were carcinomas of the bladder (1 following nephrectomy for carcinoma of the renal pelvis), and one was severe encrusted cystitis with congenital absence of one kidney. In all of these cases the urinary output was considerably reduced during the first three days following the first stage of the operation, which indicated that the ureter was partially obstructed. In 1 case the output was only 100 cc. per day for the first three days and in another case there was no output for sixty-four hours and the blood urea was 120 mgm. per cent.

The resultant ureteral stumps in these 3 cases certainly warrant the added time required to prepare them. The retrograde pyelograms show that the course of the ureter is direct and free from angulation.

lions. Thus far the procedure has not been performed bilaterally, but the authors believe that should the indication arise it might be done with equal success.

DONALD F McDONALD, M.D.

BLADDER, URETHRA AND PENIS

Ross, J. C.: Injuries of the Urinary Bladder. *Brit J Surg* 1944, 32: 44.

The communication opens with the statement that a dark shadow still hovers over the subject of injured bladder, and although the condition is not common in civilian emergency surgery it occurs in modern warfare. In civilian life bladder injuries are primarily due to automobile accidents and are almost always associated with fracture of the pelvis.

Bladder injuries are divided into three types: (1) contusions such as occur in long labor; (2) wounds, such as occur in penetrating wounds and vaginal hysterectomy; and (3) rupture such as occurs after a blow to the hypogastrium in inebriates and after overdistention during cystoscopy.

Clinically the injuries are divided into the intraperitoneal and extraperitoneal types; the former usually caused by abdominal trauma and the latter usually the result of pelvic trauma. Intraperitoneal injuries usually affect the dome and posterior wall of the bladder with resulting peritonitis; extraperitoneal injuries are usually located anteriorly, laterally or at the base of the bladder and cause extravasation with resulting pelvic cellulitis. The author confirmed these findings by work upon the cadaver.

The prognosis has been found to be in direct relation to the time interval between rupture and repair. Hamilton Bailey is quoted as having an 11 per cent mortality if operation is performed within twelve hours of injury; 55 per cent if operation is delayed for twenty-four hours; and 100 per cent if no operation is performed.

The diagnosis of ruptured bladder may be made on the basis of the history, degree of shock, inability to void, degree of stranguria, plain x-ray film and intravenous urogram, if facilities are available, and the presence of blood when a urethral catheter is passed. The author believes that cystoscopy is permissible if it is considered justifiable to insert a urethral catheter and inject sterile saline solution. He condemns the use of a 2 per cent sodium iodide for cystograms and of air for pneumocystograms.

The author advocates exploration and repair of all abdominal viscera, excision and suturing of the bladder wound and closure of the peritoneal cavity with or without drainage in cases of intraperitoneal rupture. Suprapubic drainage of the bladder is mandatory. Extraperitoneal injuries should likewise have suprapubic exploration with suprapubic drainage of the bladder. Sulfonamide preparations should be used as indicated.

Four illustrative cases with subsequent complete recovery are presented. The article is supported with an ample bibliography.

CHARLES C. HIGGINS, M.D.

MISCELLANEOUS

McCahey J. F., and Fetter J. S.: Nonfibrous Vesicoureteral Obstruction. *J Urol* Balt., 1944, 52: 216.

The authors' purpose in presenting this article is to demonstrate that vesicoureteral obstruction may exist without an organized stricture. Their view is not shared by current urologic opinion which assumes that if there is no hindrance to the passage of a ureteral catheter upward there is no hindrance to the flow of urine downward.

Five cases are presented in which pyelography demonstrated some degree of dilatation of the renal pelvis or ureter or both. In 4 of the cases the presenting symptom was renal colic; in the fifth case hematuria was the complaint. One case of renal colic following retrograde pyelography showed dilatation of the pelvis and ureters but no stricture of the ureter could be demonstrated. Two days later the intravenous pyelograms were normal. One case was treated by ureteral meatotomy and periodic dilatations with good end results. Another case of unilateral renal colic unassociated with demonstrable stricture of the ureter showed dilatation of the pelvis and ureter on the intravenous pyelogram. Catheterization of the ureters relieved the pain, and two days later the pyelograms were normal. On the intravenous pyelograms of a male with a two-month history of intermittent attacks of pain in the right loin a narrowing of the ureter at its junction with the pelvis was demonstrated. Retrograde pyelograms showed that there was no stricture in this region but periodic dilatations of the ureter resulted in relief of the painful attacks. The case in which hematuria was the presenting complaint showed bilateral hydronephrosis and hydroureter. Ureteral dilatation resulted in cessation of the hematuria.

The authors conclude on the basis of these studies that the fact that ureteral catheterization offers no difficulty is not proof that obstruction does not exist at the vesical end of the ureter. Nonfibrous vesicoureteral obstruction should be considered whenever suspicion of obstruction is justified by urologic findings. Continued dilatations may be necessary in some instances of vesicoureteral obstruction. Proper management may be not only pain-relieving but life-prolonging.

DONALD F McDONALD, M.D.

Whitehill, R. and Miller M. H.: Infestation of the Genitourinary Tract by *Strongyloides Stercoralis*: a Case Report. *Bull. Johns Hopkins Hosp.*, 1944, 75: 169.

Strongyloides stercoralis is a human parasite whose usual habitat is the small intestine. The authors recently encountered a patient in whom larvae of this worm were present in the urine. Because of the extreme rarity of this finding they thought it worth while to report the case.

A twenty-two-year-old, white single sailor was admitted to a South Pacific base hospital on April 17, 1944 because of frequency, nocturia and ur-

gency. As long as he could recall he had diurnal frequency up to 10 times. He had nocturnal enuresis until the age of sixteen. After the enuresis cleared he had nocturia 2 times every night. Also for as long as he knew he had some urgency, most marked early in the morning. For two months the urgency was more severe and there was occasional incontinence in the early morning. Five days before the admission a routine urinalysis performed in the base hospital showed a rhabditiform larva of *strongyloides stercoralis* in the centrifuged sediment. Urinary sediments were examined daily during the period of hospitalization. Over the first ten days rhabditiform larvae of *strongyloides stercoralis* were observed on 4 occasions. Occasional urines also showed a trace of albumin, a few white cells and granular casts. Urine cultures were sterile. Numerous stools were negative for *strongyloides* but contained ova of *trichuris trichiura*. The external genitalia and prostate gland were normal. The prostatic fluid was normal. The urethra was normal. There was a small slightly trabeculated area on the posterior bladder wall and a few small areas of infection in the mucosa. The trigone was slightly infected. The vesical orifice was slightly irregular with a small polyplike projection at 2 o'clock. Both ureters were patent without obstruction to a #6 whistle tip catheter with a small bulb. Retrograde pyelograms were normal.

Treatment of the *strongyloides* infestation consisted of enteric-coated capsules of gentian violet (0.06 gm) given by mouth after each meal from April 28 to May 12, 1944. After a week of this medication the symptoms of nocturia, urgency and incontinence cleared. Diurnal urinary frequency decreased to 6 times. The *strongyloides* also disappeared from the urine which was examined daily.

JOHN A. LOER, M.D.

Thompson, G. J.: The Clinical Use of Penicillin in Genitourinary Infections. *J Am Med Ass* 1944, 126: 403.

Five hundred cases in which a diagnosis was made of gonococcal infection of the urethra or its adnexa and 100 cases in which the patient suffered from various nonspecific infections of the genitourinary tract were treated by various methods of administration and various dosages of penicillin. Apparently effective and most convenient in most cases was the intramuscular injection of 20,000 units every three hours for five doses. In the gonorrheal conditions

failures were reduced to 2 per cent with this method, and even these so-called failures were, in uncomplicated gonorrheal infection, cured by subsequent courses of penicillin injection. In no case did the infecting organism prove to be penicillin-resistant, and in no case was there local reaction or systemic reaction even after large doses (500,000 units), which suggested that even larger doses might be employed. In the 10 complicated gonorrheal conditions (epididymitis, prostatitis, seminal vesiculitis) adequate penicillin medication resulted in dramatic improvement as a rule, even in the 6 patients with gonorrheal arthritis the concurrent gonorrheal infection in the urethra and prostate quickly subsided, although the joint condition was not obviously influenced.

Results in the nonspecific genitourinary infections were satisfactory in 4 patients with acute prostatitis (1 with accompanying keratitis), 6 cases of balanitis, 3 infected wound infections, to 24 of 30 patients with chronic prostatitis, in 33 of 36 with urethritis, in 7 of 8 with acute epididymitis, and in 8 of 10 with pyelonephritis. In the 3 instances of interstitial cystitis there was no improvement ascribable to the penicillin treatment. In general, improvement was not so dramatic or so rapid as in the gonorrheal infections, and medication seemed more effective against the Gram-positive organisms, nevertheless, penicillin combined with other urinary antiseptics might well be superior to other forms of treatment.

JOHN W. BRIDGMAN, M.D.

Nelson, R. A.: Penicillin in the Treatment of Granuloma Inguinale. *Am J Syph* 1944, 28: 611.

Encouraged by reports of Mahoney on the treatment of early syphilis with penicillin, 2 negro males, thirty-three and forty-three years of age, respectively, both apparently with chronic syphilis of long standing and both suffering with chronic granuloma inguinale (by Donovan bodies on biopsy) were treated with large amounts of penicillin. One was given 1,800,000 units intramuscularly in fifteen days, and the other 2,360,000 units in four and a half days.

After cessation of the treatment these patients were under observation for from thirty to forty days, and during this time no significant change was observed in the lesions—bilateral inguinal ulcers, and prepuceal ulcer in both patients. Donovan bodies were still present in the tissues of the first patient at biopsy twenty-seven days after therapy was begun.

JOHN W. BRIDGMAN, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Raizenstein, E. C. Jr. and Albright, F.: Paget's Disease: Its Pathological Physiology and the Importance of This in the Complications Arising from Fracture and Immobilization. *England J. M.*, 1944, 231-343.

Attention is called to the occurrence of acute atrophy of bone (osteoporosis) as a complication of Paget's disease and the seriousness and implications of the situation as illustrated by a detailed case history. Discussed briefly are normal bone metabolism, the metabolic abnormalities in osteoporosis as opposed to those in osteomalacia and osteitis fibrosa generalisata, the morbid anatomy of Paget's disease, and finally, a concept concerning the pathological physiology in Paget's disease.

The fact that bone lesions of Paget's disease are not generalized but spotty in their distribution, is strong evidence against the disturbance being on an endocrinological or metabolic basis. The initial lesion is bone destruction, the cause of which is obscure. The resultant weakness of the involved bones renders them less resistant to stresses and strains and this leads to a stimulation of the osteoblasts and an overproduction of bone. The repair of bone by the osteoblasts is never completed since the localized initial disorder causing bone destruction apparently persists. There results alternating destruction and repair of bone, which eventually leads to the pathognomonic pathological finding the so-called mosaic structure. In osteitis fibrosa generalisata bone is destroyed that can best be spared while in Paget's disease bone is destroyed without regard to structure.

If a bone containing Paget's disease is immobilized, as after a fracture the following events occur: the lack of stress and strain in all probability abetted by the alarm reaction of Selye, curbs the over activity of the osteoblasts and the serum phosphatase level, an index of bone formation, falls. The initial disturbance causing bone destruction persists. There results a marked imbalance between bone destruction and bone formation. The increased calcium and phosphorus coming from the bone leads to hypercalcemia and hyperphosphatemia. The capacity of the kidney to excrete calcium may be overtaxed with a resulting hypercalcemia, and if fluids are not forced the diet is not kept low in calcium and immobilization is not kept at a minimum a so-called "chemical death" from hypercalcemia may supervene. Although, in Paget's disease the broken bone becomes decalcified as a whole the fracture site shows a rapidly forming and calcifying callus. This is best explained by the hypothesis that some local influence which stimulates the osteoblasts is set loose at the site of the fracture.

EMIL C. ROBITZKE, M.D.

FRACTURES AND DISLOCATIONS

Blount, W. P. Schaefer, A. A. and Fox, G. W.: Fractures of the Femur in Children. *South. M. J.* 1944, 37: 481.

An attempt is made to correlate the findings in the literature with those in an eight year end result study of 280 cases of fracture of the femur conducted at the Milwaukee Children's Hospital. Of 281 fractures 50 were in the upper third of the femur 104 in the middle third and 37 in the lower third. Of the 104 fractures of the middle third 93 were transverse 99 oblique and 2 greenstick fractures. Comminuted fractures are much rarer in children than in adults. Transverse fractures are likely to be associated with direct trauma, while the long spiral ones are more frequently the result of indirect trauma. Greenstick fractures are less common in the middle third than in the lower third.

Traction is used routinely in the treatment of fractures of the femur in children up to the ages of four and five the overhead traction of Bryant is recommended. The Russell traction method is their choice of treatment for older children, to be used for an average period of from four to six weeks. The patient should be kept in bed for a week or more after the removal of the traction but physical therapy and the routine use of the Thomas walking caliper or cast application following traction are unnecessary. In occasional cases of skeletal traction a Kirschner wire passed through the tibia is recommended. The need for open reduction exists only in fracture at the epiphysis. Follow-up of the patient for a year or more after the fracture has healed is an important part of the treatment. Shortening and overgrowth are of considerable practical importance. Either one may be well corrected by arrest of growth of the distal femoral epiphysis of the longer femur at an appropriate age. The surgeon's duty is not fulfilled to his patient until the child has been discharged with legs of equal length several years after the date of the fracture or after closure of the epiphyseal lines.

Fractures of the lower third of the femur were found to be ideally treated by the Russell method. Epiphyseal displacements are apt to be associated with serious local circulatory disturbances and should be treated as surgical emergencies.

Fractures of the upper third of the femur are treated essentially the same as those of the middle third, with important exceptions. Failures are frequently due to the way the method is applied rather than to any fault of the method itself.

Fractures through the epiphyseal lines at either end are difficult to treat and fraught with grave danger of complications. In the authors series there were only 3 fractures of the neck and trochanter. In greenstick fractures of the trochanter in small chil-

dren, the Bryant traction or plaster fixation in abduction is adequate. In older children with fractures of the neck of the femur, it is desirable to use the abduction traction cast of Hoke. In children of twelve or more internal fixation is sometimes justified.

EMIL C. ROSENBERG, M.D.

Tyner F. H. and Hilleman W. T.: March Fracture; an Analysis of 166 Cases. *Am. J. Roentg.* 94:4, 5 65

The term march fracture, as it is generally understood, applies to those fractures of the metatarsal bones which occur without great trauma, during a march. Due importance to the theory of small repeated traumas incurred in long marches has been given but all authors agree that some other factor must be involved before march fracture occurs.

The authors studied 166 cases, securing accurate information as to the time that the fracture occurred after the beginning of the march, the foot involved, as well as which metatarsal. The blood chemistry was studied in 12 cases. Case reports are given in detail in 3 cases.

The most important factor in the production of these fractures is the increased stress on the metatarsal bones induced by muscular fatigue.

EMIL C. ROSENBERG, M.D.

Krause, G. R., and Thompson, J. R., Jr.: March Fracture; An Analysis of 200 Cases. *Am. J. Roentg.* 94:4, 53 8

The results of a study of 200 soldiers who sustained 220 march fractures of the metatarsals between May 1941 and August, 1943 are presented. Special attention is given to possible predisposing factors and the various theories which have been advanced to explain the pathogenesis of these fractures are discussed. The clinical findings and roentgenological appearances are described in detail. Forty-four per cent of the fractures were in the second metatarsal, 51 per cent in the third and 5 per cent in the fourth. The great majority of the soldiers in this series of cases were infantry men. The length of service prior to the onset of symptoms varied from one month to seven years and ten months, but 80 per cent of the fractures occurred during the first six months of service. Eighty-one per cent of the patients were between eighteen and twenty-nine years of age. Many volunteered the information that the onset of the pain occurred toward the end of a long march.

The immediate cause of the fracture is the rhythmically repeated subthreshold traumas incident to marching which acting by summation reach a point beyond the ability of the bone to bear stress. Fatigue of the calf muscle causes these subthreshold injuries to be accentuated.

A control group of 400 cases was also studied. One half of the fractures are seen and can be diagnosed before callus formation occurs. The fractures vary in extent from a narrow "hair line" to actual comminution. Seven per cent could not be diagnosed on

the first examination but were apparent on re-examination in a few days. Careful study of technically perfect roentgenograms is a requisite. Conservative treatment restores these men to duty with a minimum of time lost. EMIL C. ROSENBERG, M.D.

ORTHOPEDICS IN GENERAL

Frankel C. J.: The Treatment of Acute and Subacute Anterior Poliomyelitis. *Laryng. & Month.*, 1944, 71 451

The author has used the Kenny method of treatment of anterior poliomyelitis at the University of Virginia Hospital for over a year following Miss Kenny's tenets scrupulously. His conclusions were that the patients were made more comfortable by the applications of hot packs, and that the Kenny system of physical therapy had some merit. He could see no reason, however for the system of rigid, almost ritual-like, rules laid down by Miss Kenny nor were her explanations of various phenomena valid.

He found the Kenny treatment expensive. It required large numbers of trained personnel, few of whom are now available. In view of his indifferent results, he has discarded the full Kenny treatment and has returned to the so-called orthodox method, however he utilizes a few of the routines advocated by Miss Kenny.

The patients are being placed on firm beds, supplemented by fracture and foot boards. This is the type of bed advocated by Sister Kenny and in his opinion provides excellent immobilization.

Muscle checks are made by trained physical therapists as well as by the orthopedic staff, and all painful muscle groups are treated with the hot wet packs.

The method of application as suggested by Sister Kenny carries with it practically no danger of skin burn and therefore is to be recommended over methods more easily applied. However the author does not apply the packs more often than four or five times daily because personnel requirements are sharply with more numerous applications than this. Prostigmine, methyl sulfate and atropine are being administered subcutaneously for one dose and after that prostigmine bromide and atropine are given three times daily. Recent work has shown that these drugs play a definite part in relieving muscle spasm.

When muscle pain subsides physical therapy is instituted. Muscle checks are made about once every month and hot packs are discontinued with the disappearance of pain and limitation of motion.

As soon as is feasible ambulatory braces are applied.

Cases which show no progress within a period of six months are generally considered hopeless so far as future recovery of the affected parts is concerned, and ambulatory braces should be applied. No surgery is contemplated for at least one year or eighteen months after the onset of the disease.

Precautions should be taken against exposure to flies. These insects are known to be able to carry

and distribute the virus particularly when excreta from patients in the acute stage of the disease has not been disposed of properly.

An examination should be made of the extremities by practitioners to determine the sites for the hot packs. Both legs should be lifted carefully from the bed and if the patient complains of pain in the hamstring area that site should be noted for application of the hot packs. The feet should be dorsiflexed to demonstrate pain in the calf group. Sitting the patient up and flexing the neck will demonstrate involvement of the neck muscles. Abduction of the arms will demonstrate pain or involvement in the pectoral or shoulder area, and movement of the elbow and wrist will bring out pain if present in those parts.

The author has found that the rigid bed is more simple and appears to be more satisfactory than splints or casts. There is, however, no valid objection to the use of these splints.

Other methods of heat have been tried they include hot paraffin diathermy infrared electric pads hot water bottles, and heat cradles but none have as yet proved as efficacious as the hot woolen pack when well wrung out.

ROBERT P. MONTGOMERY, M.D.

Chance, B. Jr.: Evaluation of the Kenny Method in the Treatment of Chronic Infantile Paralysis. *Pennsylvania M. J.*, 1944, 47: 975

The author evaluates 23 cases of chronic infantile paralysis treated according to the Kenny method. The patients selected had their disease from one to five years and had previously received the best of orthodox physical therapy. They were all carefully evaluated on the basis of their previous rate of improvement, and the majority had in the author's opinion reached a stage in which little or no further improvement could be expected with the usual type

of physical therapy. All of the cases displayed the following symptoms: (1) muscle spasm, (2) incoordination, and (3) loss of tone, reflexes and the ability of voluntary contraction described under the Kenny concept as "mental alienation."

Two forms of treatment were carried out. The first was the application of hot fomentations for the relief of muscle spasm. These were made of wool blanket material wrung out of boiling water and applied directly to the skin in packs for two-hour periods. The second phase of the treatment was that of muscle education. Individual muscle function was stressed and attempts were made to make the patient aware of the correct action of each muscle. Careful records were kept at all times. Limitation in joint motion was measured and photographed at frequent intervals. Increase in the range of joint motion was taken to be an indication of release of the muscle spasm. In all cases the previous treatment and the rate of improvement were well known and all of them were treated by the same technicians as previously.

After from three to eight months of this treatment the author noted a decrease in muscle spasm in all of the cases. Release of muscle contracture was noted in all but 7 cases. Seventeen of the cases showed marked improvement and all of the cases showed some over all improvement. One factor noted in the improvement was the excellent psychological influence of the treatment. The author stresses that the Kenny treatment must be directed at the clinical manifestations of spasm and carried out only when indicated. Cases must be carefully selected if good results are to be obtained. Complete prolonged paralysis of antagonistic muscle groups associated with the destruction of anterior horn cells in the spinal cord cannot be helped either by the Kenny treatment or any other type of physical therapy now in use.

DAVID H. LEVINTHAL, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Elkin D. C.: *Vascular Injuries of Warfare*. (1st ed.) Surg 1944, 120-184.

Vascular war injuries may be classified in three groups: the first consists of those cases in which the blood vessel is either completely severed or in such a state of vasospasm as to cause death of the tissues it supplies; the second consists of cases in which an already existing vascular lesion is activated by the trauma of military service; and the third consists of cases of arteriovenous fistula or aneurysm.

Arterial occlusion may be either partial or complete. With total occlusion gangrene or ischemic paralysis will result unless an adequate collateral circulation is established. Arterial spasm results from trauma to the vessel wall itself or to the tissues about it. Vasospasm may be segmental or sufficiently reflex in character to produce a total vasomotor imbalance of an extremity. If this condition is not relieved, thrombosis with fibrosis, atrophy and deformity and even gangrene will develop. Reflex vasoconstrictor impulses may be removed by periaxillary sympathectomy, ganglionectomy or procaine sympathetic block.

Pre-existing vascular lesions such as vascular nevi, congenital telangiectasia, or angiomas, may become circoid aneurysms, pulsating angiomas, and arteriovenous aneurysms when activated by trauma. Twelve cases with such histories are reported. These lesions may be treated in a variety of ways, i.e., ligation of the main blood supply, multiple circumferential sutures, or the injection of sclerotic agents.

Early in the inception of arteriovenous fistula, no symptoms or physical signs may be noted other than an auscultatory bruit. Other signs and symptoms may be masked until the edema or the hematoma of trauma subsides. An arteriovenous fistula can be differentiated from a false arterial aneurysm by detection of a continuous thrill and bruit accentuated

Fig. 2. Schematic drawing to show communications between an artery and a vein, illustrating the necessity of not only quadruplication but complete excision with all branches.

in systole. Other characteristic manifestations of an arteriovenous fistula are dilatation of the vein about and distal to the fistula, and slowing of the pulse with obliteration and trophic changes of the extremity. With large fistulas, cardiac dilatation may be demonstrated with x-rays. Treatment should be deferred to allow for the maximal development of a collateral circulation unless cardiac failure is imminent. To be successful, operation requires that the fistula be completely excised or obliterated. Ligation alone is often followed by recurrence through the collateral circulation. When excision is not possible, the fistula may be infolded by heavy mattress sutures. The operation should be done without the use of a tourniquet.

In the discussion BUCK stated that vasospasm may develop after nonpenetrating wounds, simple fractures of the long bones after severe wounds, and the presence of various types of superficial infections, such as trichophytosis. Vasospasm may be the deciding factor in gangrene of a part and influence the development of gas infection. Sympathectomy should be done more commonly.

The Alatas technique for the treatment of arteriovenous aneurysms was discussed and RIVES demonstrated the value of obliterative aneurysmorrhaphy by a series of case reports and claimed that it offered the best method of preservation of the collateral circulation and required a minimum of dissection.

WATKINS referred to the work of Blakemore and Lord who have devised a nonsuture method of bridging gaps in arteries with vein grafts on vitallium tubes which permits re-establishment of arterial continuity.

BENJAMIN G. P. SHERIDAN, M.D.

Bigger I. A.: The Treatment of Traumatic Aneurysms and Arteriovenous Fistulae. Arch Surg 1944, 49-170.

Twenty-nine cases of traumatic arterial aneurysm or arteriovenous fistula have been studied by the

Fig. 1. Showing enlargement of the heart and return to normal size following excision of an arteriovenous aneurysm. (Courtesy of J. B. Lippincott Co.)

authors. Thirteen of the patients had arteriovenous fistulae 15 had arterial aneurysms and 1 had an aneurysm of the abdominal aorta and a fistula between the aorta and the vena cava.

A traumatic arterial aneurysm is usually the result of injury to an artery deeply embedded in the soft tissues. In the early state the lesion is called a pulsating hematoma, but when it becomes well localized and spherical it is called a traumatic or false aneurysm. This article is concerned with the latter condition.

It is generally agreed that once localization has occurred, surgical intervention should be delayed to permit improvement in the collateral circulation and disappearance of bacteria from the adjacent tissues. Unless complications which demand earlier operation arise, conservative treatment should be continued for at least from six to eight weeks.

The interruption of nerve function by the pressure of an expanding aneurysm is not necessarily an indication for excision of the aneurysmal sac, for any procedure which relieves pressure such as aneurysmorrhaphy if performed early will be followed by return of nerve function. It is important therefore, that a careful neurological examination be done on any patient with a traumatic vascular lesion especially when the subclavian axillary brachial, or popliteal artery is involved.

Infection alone may be treated conservatively but careful watch must be kept for secondary hemorrhage and if it occurs immediate operation is indicated. The type of operation is dependent on the extent and severity of the infection as well as on the location of the aneurysm. If the infection is mild and especially if the aneurysm is so located that exposure of the artery proximal to the infection is difficult or fraught with unusual danger the sac may be opened and the artery doubly ligated and completely divided between the ligatures. If on the other hand the artery can be readily exposed proximal to the area of infection and obstructed without interference with essential collateral channels proximal ligation of the artery and of the concomitant vein may be the treatment of choice.

Excision of an aneurysmal sac is more certain to cure the lesion than aneurysmorrhaphy but has the disadvantage of destroying more collateral channels than does the intrasaccular operation. It is reasonable to assume that interference with the collateral arteries would increase the danger of ischemic gangrene and would also increase the degree of chronic circulatory deficiency.

An atypical or incomplete operation may result in cure of a traumatic aneurysm but an arteriovenous fistula is rarely cured except by complete ligation of the involved vessels and excision of the fistulous area or by suture of the artery. If the latter procedure is employed it is usually better to ligate the vein above and below the fistula and then to open the vein and suture the artery under direct vision.

Evidence presented by the author indicates that although the excellent collateral circulation developed

in the presence of an arteriovenous fistula makes the danger of ischemic gangrene almost negligible it does not prevent persistent circulatory difficulty when main vessels are ligated and resected. It is therefore suggested that when such important vessels as the carotid artery and jugular vein, the common femoral vessels or the popliteal vessels are the site of an arteriovenous fistula, transvenous repair of the artery be employed if there are no contraindications. The most important contraindication to arterial suture is calcification of the wall of the artery in the area to be sutured.

When main vessels are obstructed especially those to the lower extremity permanent interruption of the sympathetic nerves to that extremity may help prevent chronic circulatory deficiency distal to the obstruction.

JOSEPH K. NARAT, M.D.

BLOOD TRANSFUSION

Messle, E., Stillerman, H. S., Wright, C., and Minnich V: The Effect of the Administration of Digitalis on the Coagulability of Human Blood. *Arch. Int. M.*, 1944, 74: 173

Oral therapeutic doses of digitalis caused the clotting time determined by the Lee-White method to be accelerated in each of 24 patients during the period of administration of the drug. The prothrombin time, measured, in about half of the cases by the Smith bedside method was not altered nor were changes observed in clot retraction. After the administration of digitalis was discontinued the coagulation time increased in the majority of the 13 patients so studied, even though the drug had not yet been completely excreted during the period of observation. It is suggested that digitaloid drugs may have a thromboplastic effect on the clotting mechanism.

WALTER H. NADLER, M.D.

Crawford, T., and Nessim, J. R.: Unusual Response to Dicumarol Therapy. *Lancet*, Lond. 1944, 247: 404.

The synthetic antithrombotic substance dicumarol is coming increasingly into use in cases of venous thrombosis and in other conditions in which it is desired to diminish the clotting power of the blood. The case reported shows some of the difficulties which may arise during the use of the drug. It also illustrates that dicumarol may take very much longer than the usual forty-eight hours to act and its effect may last days after dosage ceases.

A soldier, aged nineteen years, was admitted to the ophthalmic department of a military hospital complaining of flashes of light before his eyes and increasing blurring of vision during the last three months. There was nothing relevant in his previous health or family history.

He was a young man of excellent physique and in good general condition. His blood pressure reading was 130/80 mm. Hg. Nothing abnormal was detected on physical examination with the exception of the eye findings. Vision in the right eye

was reduced to perception of hand movements only at 3 ft., while that in the left eye was 6/60. Bilateral thrombosis of the retinal veins was found.

In view of the fact that the thrombotic process was extending and vision deteriorating, it was decided to administer a course of dicumarol with the object of diminishing the clotting power of the blood and in the hope of checking the progress of the disease. Treatment was begun on September 30, 1943 with a dose of 300 mgm. of dicumarol and thereafter 200 mgm. were given each day after the prothrombin time had been determined. The prothrombin time increased disappointingly slowly, reaching only thirty seconds after thirteen days of treatment. Because of this slow response the dose of dicumarol was increased to 225 mgm. on the fourteenth day and to 300 mgm. on each of the three succeeding days. The drug was then discontinued because of the development of signs of intolerance. On the tenth day of treatment the patient complained of headache, nausea and constipation. On the thirteenth day there was complaint of backache. On the seventeenth and last day of the dicumarol treatment he developed pain in the abdomen and back, and vomited several times.

When the dicumarol administration was stopped the prothrombin time had reached thirty-six seconds. Two days later it rose to thirty-nine seconds and gross hematuria began. Later this day a subconjunctival hemorrhage appeared in the right eye and a transfusion of a pint of fresh blood was then given. This reduced the prothrombin time to twenty-nine seconds but free hematuria continued. On the fourth day after cessation of the treatment the prothrombin time reached a peak figure of forty-seven seconds. Subconjunctival hemorrhage had now appeared in the left eye and had extended in the right. Hematuria was more profuse. A transfusion of 2 pints of fresh blood was given and the prothrombin time fell to twenty-five seconds. Two days later however it had again increased to thirty-five seconds and a third and final transfusion of 2 pints of fresh blood was given. Thereafter the prothrombin time fell to its original value of twenty-two seconds and remained at this level with only minor fluctuations. Gross hematuria continued for a further five days (eleven days in all) after which there was microscopic hematuria for six days before the urine became normal. All symptoms associated with the dicumarol gradually subsided. Six days after cessation of treatment the blood pressure had fallen from 160/90. The drug appeared to be without effect on the retinal venous thrombosis.

The points of interest arising from this case are the delay in the development of the antithrombotic action of dicumarol in a patient who later reacted strongly to the drug; the signs of gastric and renal irritation which preceded the hemorrhage and the long period of action of the drug after its administration had been stopped.

It is evident that at present great caution must be exercised in increasing the dose of dicumarol when

the response to ordinary dosage is unusually prolonged. In addition it is clear that in using this drug the physician or surgeon must be prepared to administer repeated transfusions of fresh blood should hemorrhage occur and a close watch must be kept on the prothrombin time for at least a week after administration of the drug has ceased. The action of dicumarol is in contrast to the more physiological action of heparin.

JOHN E. KIRKPATRICK, M.D.

Scott R. A. M., and Lissimore, N.: *Mesenteric Thromboses in Lymphatic Leucemia Treated with Dicumarol*. *Lancet* Lond. 1944, 247-49.

The authors report the case of an active man aged sixty-two years who had been healthy until at the age of forty-five he noticed shortness of breath on climbing, and increasing fatigue at the end of the day. Occasionally he had taken iron for anemia.

Episodes of cramping pain in the abdomen, of short duration began in July 1941. On one occasion a few months later he was seized with abdominal pain and vomited "coffee grounds." He recovered promptly. On February 12, 1942, he had violent abdominal pain and the familiar vomiting and diarrhea which became more severe. He went into shock which subsided with the administration of frequent doses of morphine and atropine. Another attack occurred on February 26, 1942.

A surgeon diagnosed an acute abdomen and a laparotomy was performed. A thrombus in a branch of the superior mesenteric vein was found; it was causing an acute intestinal obstruction of the terminal ileum. The spleen was enlarged. Due to the emergency a complete blood count was not performed until after surgery. (The total leucocyte count was 180,000, 95 per cent of these cells being lymphocytes.)

Attack followed attack until a two-weeks course of x-ray therapy was given to the spleen and enlarged glands of the neck, beginning on August 15, 1942. This improved the blood picture and reduced the total leucocyte count to 11,200 (50 per cent lymphocytes) by August 26, 1942. Between attacks of tracheitis, colds and quinsy, and frequent abdominal cramps, the patient remained in poor health.

On June 25, 1943, treatment with dicumarol was started with the hope of preventing the complicating factor of thrombosis, and under continuous dicumarol treatment the patient has enjoyed remarkably active good health with no abdominal pain. The lymphocyte series has been gradually increasing since radiation but without any clinical deterioration. During the treatment with dicumarol there has been no evidence of hemorrhage in any part of the body.

JOHN E. KIRKPATRICK, M.D.

Hardy J. D., and Godfrey L. Jr.: *The Effect of Intravenous Fluids on Dehydrated Patients and on Normal Subjects*. *J. Am. M. Ass.*, 1944, 26-31.

The authors note the effect of intravenous fluids on the cardiac output, stroke volume, pulse rate, and

blood pressure of a group of dehydrated patients in comparison with similar observations made in a group of subjects not demonstrably dehydrated. Whether dehydration is the result of vomiting, diarrhea, inability to swallow, or electrolyte derangement such as occurs in diabetic acidosis, the intravenous administration of fluids is the mode of therapy usually relied on to restore the normal state of hydration and electrolyte balance. The dehydrated individuals experienced a pronounced increase in cardiac output after the infusions, while the normal subjects presented little or no such rise.

Blood was first drawn for determinations of the serum protein, serum chloride, and blood urea nitrogen. The cardiac output was calculated by the urea method and the correction of Courmand, Ranges, and Riley was employed. The technique used is described in detail. Following the readings of cardiac output, stroke volume, pulse rate, and blood pressure, 2500 cc. of intravenous fluids were administered at a rate of about 20 cc. per minute. The first liter of fluid was usually an isotonic solution of sodium chloride; the second, 5 per cent dextrose in isotonic solution of sodium chloride; and the third, 5 per cent dextrose in water. Ballistocardiograms, pulse-rate, and blood pressure readings were taken after each liter of fluid was administered.

The authors note that the cardiac output of the dehydrated group increased substantially with the administration of intravenous fluids while that of the normal group underwent no such rise. The 2500 cc. of fluid administered intravenously provoked no subjective symptoms in any of the normal subjects but it was followed by a prompt diuresis.

The normal persons had to void frequently during the infusion and the dehydrated patients did not. In the latter group more fluid was retained in the body. The fluids given intravenously doubtless increased the circulating blood volume in most of the dehydrated patients described here. Intravenous fluids may cause effects in diseased subjects very different from those observed in healthy persons.

In conclusion, the authors note that the feeling of general well-being so often experienced by the dehydrated patient after receiving fluid intravenously is accompanied by concomitant objective changes in the circulatory dynamics. The maximum effect is quite often produced by the first liter of fluid and this amount may be sufficient in such instances in which there is danger of giving too much fluid intravenously. When giving fluids intravenously to dehydrated patients, one should remain aware of the increased work which such therapy imposes on their hearts.

Kozoll, D. D., Popper, H., Stelgmann, F., and Volk, B. W.: *The Use of Gelatin Solutions in the Treatment of Human Shock*. *Am. J. Med. Sci.*, 1944, 908-1421.

Since human plasma or blood is not available in unlimited quantities, plasma substitutes are being

developed from macromolecular substances. The first to be used was gum acacia, which has been discarded because it is deposited in the liver. Pectin, isinglass, and gelatin have been recommended.

This study deals with the results of treatment of shock in human beings by the administration of gelatin solutions. Gelatin is a mixture of various proteins, which vary in type and molecular size in different types of gelatins according to their source and preparation. It can be prepared as a nontoxic solution isotonic to plasma and somewhat more viscous than it. Experiments on rats, rabbits and dogs at the Upjohn Research Laboratories, Kalamazoo, Michigan, have demonstrated that the gelatin solution used in these studies is well tolerated without toxic effects. The methods used in treating 52 patients are described by the authors.

In none of the patients was there any evidence of pyrogenic or other untoward reaction to the gelatin administration. No chills, abrupt rise of temperature, or complaints of pain were noted. No hemorrhagic tendencies were apparent. After the gelatin infusion, whole blood or plasma was given repeatedly without any complications. The mean of the hemoglobin, plasma density, total protein, nitrogen, and hematocrit dropped markedly after the gelatin infusion and remained below control value for twenty-four hours. The hemoglobin decreased slightly less and the total protein nitrogen significantly less than the hematocrit. The nonprotein nitrogen showed on the average an increase immediately and twenty-four hours later but it was not statistically significant because of marked deviations in both directions.

The sedimentation rate, which was markedly elevated before treatment, rose consistently the increase being statistically significant. The rise was maintained from twenty-four hours to five days. This increase in the sedimentation rate was not influenced by dextrose, saline solution, blood, or plasma given following the gelatin.

The systolic and diastolic blood pressures, which were markedly reduced before treatment, rose upon completion of the gelatin infusion and were maintained. An improvement of the pulse was observed, as well as a change in the skin from a cool and clammy condition to a warm and dry one. No change in temperature or respiration was noted. In the great majority of cases, one gelatin infusion relieved extreme as well as moderate shock without any additional therapy.

In summarizing, the authors note that the administration of gelatin to patients in shock is a safe procedure. The only undesirable effect is the effect on the erythrocytes. The increase of the sedimentation rate, which is generally found upon injection of macromolecular substances, is an important disadvantage after marked hemorrhage. In cases of shock without severe hemorrhage, no evidence was found that the increased sedimentation rate was of clinical significance. No signs of venous thrombosis were noted. Absence of a low degree of antigenicity of gelatin has been demonstrated previously as well as

the fact that gelatin is not utilized in tissues to a significant degree in contrast to other macromolecular substances. Gelatin solution is an effective blood-modulating agent. The solution of the red cells as judged from hematocrit and hemoglobin appears more marked than that of the plasma proteins. One thousand cubic centimeters of a 5 per cent gelatin in normal saline solution seemed sufficient to the authors in most cases.

In conclusion, the authors note that the results of future investigations will decide whether the nitrogen content of gelatin has nutritional value after its intravenous administration in shock, as it was found to have in experimental animals.

HENRIET F. THOMPSON, M.D.

MISCELLANEOUS

Glaser, H. Congenital Hereditary Lymphedema (Milroy's Disease). *J. Pediat.* St. Louis 1944, 5: 337.

The author reviews 2 cases of congenital, hereditary lymphedema observed at the Milwaukee Children's Hospital. The condition is extremely rare and the author is unable to find more than 50 families so affected which have been reported in the literature. In view of some very excellent reports on several generations, the hereditary tendency seems to be proved. The etiology seems to be entirely unknown and congenital malformation of the lymph vessels is widely accepted. Some possible causes are somatic disturbances, a focus or lymphatic obstruction or thrombosis.

The condition consists of a firm pitting edema affecting part of or the whole leg, or both legs, and never extending above the upper femoral ligament. There usually are no pain, attack or general inflammation.

Two and no constitutional symptoms. The edema appears to be physiological in color and texture.

The laboratory findings, including blood chemistry and counts, urinalysis, basal metabolism, the Aldrich McClure test, and x-ray pictures of the limbs are all normal. The pictures of the skin show swelling and increased trabeculation of the subcutaneous tissues with radial arrangement of the trabeculae.

The few lymphatics reported in the lymphatic enlarged spaces which may be lymphatic in origin, increase of subcutaneous tissue. The course is chronic and progressive unless treated. With treatment the edema can be reduced but it returns to its dimensions soon after regular activity is taken up and compression of the limb discontinued. Bandaging will reduce the swelling if it is done correctly, but is unsuccessful. The best results have been obtained with adhesive tape or pure rubber roller bandages. Elastic bandages and stockings as well as various boots have been tried. In later stages progressive fibrosis reduces the compression effect. The operative procedures of the type of the lymphatic operation or that of astrunk have been employed in severe cases. Other surgical procedures are the insertion of silk or of cellophane. Sympathectomy has been attempted but was considered useless.

The author reviews in detail 2 cases at the Milwaukee Children's Hospital and the treatment employed. The effect of the treatment was temporary. The histological examination of the sections of one patient proved the presence of definite tissue changes, and ruled out the possibility of the lymphatic fluid or blood. The clinical and laboratory report substantiate the fact that this is not a constitutional disorder.

SURGICAL TECHNIQUE

WAR SURGERY

Sergeant, T. R. and Morton W. A.: Delayed Suture of Soft Tissue Wounds. *Lancet* Lond. 1944, 147
333

Soft-tissue wounds uncomplicated by fractures or other serious injuries constitute half of all battle casualties. The desirability of the early recovery of such a large group is obvious. In the Allied armies the accepted treatment is early débridement followed, if there is not too much skin loss by delayed suture. Early closure of the skin not only prevents infection but also decreases the fibrosis and scarring that accompany slow healing.

The importance of suturing the 'little wound' should be emphasized, particularly if the patient has no other injury often it appears insignificant and in the press of more urgent work is not given adequate consideration. With suture the wound should be healed in from seven to ten days and the patient returned to duty without suture, infection develops epithelialization is retarded and the insignificant 'little wound' takes several weeks to heal. Under ideal conditions the average rate of growth of epithelium from the wound margin is one-eighth inch a week, but infection retards this growth either along the whole margin or irregularly so that one or more areas of infected granulation tissue may persist for weeks. The longer a wound remains open with mild superficial infection the more fibrosis develops deep in it and interferes with the blood supply of the new epithelium epithelialization of the central portion of the defect is thus extremely slow and the new skin is prone to break down under the wear and tear of exercise.

The advantages of early closure of wounds cannot be denied but the decision as to when and how to close them is not always easy. To ascertain the indications for suture the authors made a survey of 143 soft tissue wounds, 100 of which were closed by delayed suture. The operations were performed by staff members of a Canadian General Hospital in the Mediterranean area during a six month period.

The wounds were from three to one hundred and thirty four days old and from $\frac{1}{4}$ inch in diameter to 9 inches long deeply involving muscle. In a sutured wound, complete healing within fourteen days was termed "success" complete healing within twenty-one days "partial success" and healing in more than twenty-one days failure. In the 100 cases there was complete healing in 53 within four ten days, partially successful healing in 20 within twenty-one days and no healing in 27 after twenty one days.

It is considered a mistake to close a wound under five days from the time of wounding since it is impossible to tell what degree of superficial infection is present, what additional necrosis may result from

the trauma of the missile, or whether a deep-seated infection or foreign body reaction will develop.

If no contraindications are evident after five days have elapsed the wound should be sutured as soon as possible. In the first nine days the walls of the wound are soft and pliable and can be easily approximated provided there is not too much loss of tissue. Between the eleventh and fifteenth days granulation tissue appears on the floor of the wound and a thin bluish line of new epithelium can be seen growing from the skin margins. This means that the walls have already lost much of their pliability the skin margins have become adherent to the granulation tissue on the floor and approximation may necessitate additional surgery such as undercutting of the margins.

The wounds which healed best had undergone early débridement consisting in minimal excision of the skin adequate exposure of the depths excision of all the damaged soft tissues and removal of all the foreign material. The cleanest wounds were those covered by a very light plaster-of Paris cast.

Cultures taken from the 100 wounds (79 of those that were subsequently sutured and 21 of the unsutured) showed that the staphylococcus aureus was the commonest offender the streptococcus haemolyticus coming next the latter however was not prominent until after twenty-one days. Up to ten days only single strains of bacteria were found, the combinations seen later almost always included the staphylococcus aureus with a diptheroid. Criteria for the suture of wounds should be based upon the clinical appearance not on the bacteriological findings.

After from five to nine days a débrided wound which is suitable for suture should show the surrounding tissues to be normal on palpation not indurated and not tender and the skin margins should show no reaction. If tenderness, reddening of the skin margins purulent discharge or necrotic tags of muscle, fat, or skin are present, suture is inadvisable.

Wounds from ten to twenty-one days old which are suitable for suture should show no sign of induration or tenderness, and the skin should be soft and pliable up to the very margin of the wound.

Before suture of wounds over twenty-one days old is done the surrounding skin should be pliable. A shelving margin with a growing border of new epithelium should be present. The base should be covered by smooth granular beefy red granulation tissue, and the exudate should no more than faintly stain gauze kept on the wound for twelve hours.

Dry gauze applied with firm pressure is the best postoperative dressing. Immobilization by plaster of Paris splints may be necessary.

Failures were commoner with wounds on the anterior surface of the leg the lateral aspect of the thigh and greater trochanter the upper medial por

tions of the buttocks and on the back. The factors concerned appeared to be tightness of the skin tension of the deep fascia, inability to immobilize the part completely and difficulty in preventing the patient from lying on the wound.

The antiseptic treatment which seemed most successful was the use of 1:4 eusol solution until the purulent exudate had diminished, then a change to 5 per cent saline solution and finally alternation of these solutions every few days.

Approximately two-thirds of the wounds were influenced with a sulfonamide powder at the time of the delayed suture and one third were not. Suture of wounds over ten days old was not appreciably affected by this treatment. For the wounds from five to nine days old however the sulfonamide powders seem to have been beneficial. It seemed expedient to emphasize that the local use of sulfonamide can never be anything but an adjunct to good surgery.

STEPHEN A. ZILMAN, M.D.

Rogers, L. S.: Abdominal Surgery In Forward Areas: Observations Made In A Casualty-Clearing Station, 1941-1942. *Austral N Zealand J Surg* 944, 4 37

The place best suited for abdominal surgery is the casualty-clearing station separate resuscitation units working in advance of this station would only delay the arrival of the patient to the abdominal surgeon. The chief resuscitation ward is the preoperative ward of a casualty-clearing station. The x-ray plant is placed at the distal end of the preoperative ward in every case of penetrating wound of chest, buttock and upper thigh an x-ray examination in one plane is carried out as a routine. Two planes are used only in difficult cases.

If under resuscitative measures (sedation, blood transfusion, warmth) the patient improves and says that he feels better operation is delayed until the diastolic pressure reaches 80 and the systolic 100. If there is no improvement, immediate operation is undertaken, after 5 pints of blood have been given to stop the internal hemorrhage. The time factor of itself does not preclude operation. Patients whose condition is three days old have been saved.

The incision varies with the condition found or anticipated, once an opening has been made into the abdomen, however, all free fluid is rapidly aspirated also that in the pelvis. Control of the bleeding is undertaken first, if it is coming from the spleen splenectomy is done, otherwise, undersewing with mattress sutures is done. All holes into the chest cavity are closed first. In exploration the start is made in the large intestine. If a hole is found lateral mobilization and exteriorization of the part is in order. Next the ileocecal junction and the small intestine and stomach are explored, thoroughly and rapidly each hole being clamped with a Poirier forceps. Finally the bladder is inspected. Repair is always better than resection when it is possible. End-to-end junction after resection is best for the small intestine. Simple suture is done. A Miller

Abbot tube should be guided through the pylorus at the end of the operation. In wounds of the rectum, bladder and sigmoid colon the Trendelenburg position is used only after the pelvis has been aspirated. The pelvis should be drained after every perforating wound. Blood collection in the area often means a pelvic abscess later. The pelvic drain should be clamped when the operation is finished. Sulfadiazine emulsion is injected, and this is then washed into the abdominal cavity by a further injection of 30 cc. of sterile saline solution.

Postoperative treatment begins at once in all abdominal cases with continuous gastric lavage and suction. The nasal route is the best. With the tube in place the patient is allowed to drink whenever he feels like it. Three times a day the stomach tube is disconnected, and 500 cc. of hot sodium-bicarbonate solution are injected. Lavage and suction are maintained until intestinal movements are continually heard and flatus and feces are passed. Fluid balance is carefully watched. Fluids are given parenterally for the first two or three days, then a continuous rectal drip. Flatus competitions are encouraged. Morphine in doses of $\frac{3}{4}$ gr every four hours and $\frac{1}{4}$ gr at night is given continually for the first two days (sleep and rest to the bowel are necessary). The abdomen is inspected twice a day and hot copious bowel washouts with postural treatment are begun the moment distention appears. When intestinal movements are heard continually and flatus is being passed, the stomach tube is clamped and fluids are allowed by mouth. If there is no residue at the end of four hours, the tube may be removed. If vomiting occurs the tube is reinserted immediately.

Sulfathiazole is given intravenously while suction continues. A second dose of sulfadiazine emulsion injected down the pelvic tube has been found to cause intense pain and dysuria for twenty-four hours it has therefore been given up.

Danger signs in abdominal cases are these: persistent hiccup which starts even during operation; slow persistent distention with a silent abdomen; continual anxiety and a high pulse rate and diminution of the urinary output. In retroperitoneal wounds distention starts very early and is progressive. Stomach suction is not usually sufficient to deal with the ileus. Semi-erect position of the penis is often present and is a bad sign. In these wounds the prognosis is usually bad. JOHN W. BARNARD, M.D.

Macdonald: Observations on Battle-Casualty Compound Fractures and Joint Injuries in the Middle East. *N Zealand M J* 944, 43 7

Macdonald describes his experiences as an orthopedic surgeon with a New Zealand hospital unit in the Middle East during 1941-1942 and part of 1943, especially in regard to battle-casualty compound fractures and joint injuries. It must be understood that continuity of treatment by any one man of any one serious long-distance case seldom occurred.

The author is emphatic in stating that primary skin suture holds no place at all in front line surgery.

(as it occurred in the Western Desert) It became standard technique to carry out simple surgical toilet of the wound followed by the insufflation of 10 gm of sulfanilamide and the application of vaseline gauze without suture of the skin edges. He condemns the use of the vaseline plug as it was found that many wounds were packed too tightly and too voluminously. He recommends that a minimum amount of vaseline gauze be used, enough only to keep the wound edges gently open. Débridement as we know it was not practiced. It was found sufficient to remove only the obviously devitalized tissue and to open up for drainage any of the deeper spaces which might have become infected and then have pocketed.

The Thomas Splint, if it ever needed vindication has certainly received it in the Middle East. Macdonald states that all patients with femur and knee-joint injuries on whom the splint was correctly applied, traveled more comfortably and arrived in better condition than did those which were put in plaster. The Tobruk plaster (Thomas splints with added plaster-of-Paris) came out of this campaign. The badly fractured humerus was put up in treble V shaped plaster, the elbow at 90 degrees, the forearm in neutral rotation and the whole unit then bound across the front of the chest. Knee joints were treated on Thomas splints with fixed skin traction.

The author concludes by stating that the factors responsible for the good results were massive transfusions, sulfanilamide, infrequent dressings, avoidance of primary skin suture, efficient splinting, recognition of the fact that the first operation is the one which counts, and sending the surgeon to the patient rather than sending the patient back to the surgeon.

Churchill, E. D. The Surgical Management of the Wounded in the Mediterranean Theater at the Time of the Fall of Rome. *Ann. Surg.* 1944, 120: 268.

Foreword by Brig. General Fred W. Rankin, M.C. As Surgical Consultant to the North African and Mediterranean Theater of Operations and representative of this group, Colonel Churchill has done more than improve the quality of surgery performed in this Theater. Uniquely equipped to perform his mission and imbued with the true scientific spirit, he early recognized the inadequacy of certain preformed concepts in the surgical management of the wounded. With this flexibility of mind and with an elastic organization, he has utilized an investigative approach and drawn upon battlefield experience to evolve more rational and effective methods in the surgical care of the wounded. In this article, he has epitomized these observations and principles which constitute not only a contribution to war surgery but also to the advancement of medical science.

The surgery of warfare is divided into three phases of management. The initial and reparative phases of wound treatment are given overseas; the recon-

structive phase is administered in the zone of the interior.

INITIAL SURGERY

Initial surgery in the battle area is intended to preserve life and limb by correcting the abnormal physiology resulting from the loss of blood and other body fluids. Included in the procedure are resuscitation and chemotherapy for the limitation and restriction of infection. Resuscitation makes possible the transportation of the casualty and permits him to withstand essential surgical operations. In the divisional forward areas, plasma is used. However, after admission to the hospital, it is replaced by whole blood which is procured and processed by special units. Over a four month period, 16,000 pints of blood were delivered to the Fifth Army on the Anzio beachhead. Only Type O blood (universal donor) with an agglutinin titer below 64 and a seven-day expiration date was used. Other types of blood are maintained by unit blood banks in evacuation hospitals. The prevention of infection is attempted by means of débridement of the wound. Oftentimes it is impossible to recognize all devitalized tissue. Therefore, primary closure by wound suture is not performed. Only provisional or temporary fixation of fractures is performed because of the necessity of evacuation. The value of local sulfonamide chemotherapy is questionable. However, penicillin therapy is administered to all battle casualties except the slightly injured. Topically, it is used only in the meninges, serous cavities, and joints. Parenterally, it is continued beyond the expected period of infection. However, chemotherapeutic agents cannot be expected to prevent septic decomposition or render sterile any devitalized or avascular tissue. Nevertheless, penicillin has enlarged the scope of military surgery and opened vast new fields in wound management.

Initial surgery is not hasty, slap-dash surgery, but really precision surgery of a highly specialized type. It often involves the treatment of multiple serious wounds that require the co-ordination of surgical specialties. At the divisional clearing station, first priority cases are evacuated for treatment to a nearby first priority surgical hospital. These hospitals are manned by highly trained and experienced personnel comprising an Auxiliary Surgical Group.

REPARATIVE SURGERY

As a result of the use of penicillin, reparative surgery at the base hospitals has been completely revolutionized in every surgical specialty. It must be distinguished from reconstructive surgery, which is a function of hospitals in the zone of the interior. At these base hospitals, at least 25,000 wounds were closed by suture with healing in 95 per cent and no loss of life or limb. Wounds are closed by secondary suture as early as the fourth day after injury solely on appraisal of the gross appearance of the tissues after removal of the evacuation hospital dressing. Qualitative or quantitative bacteriologic analyses of

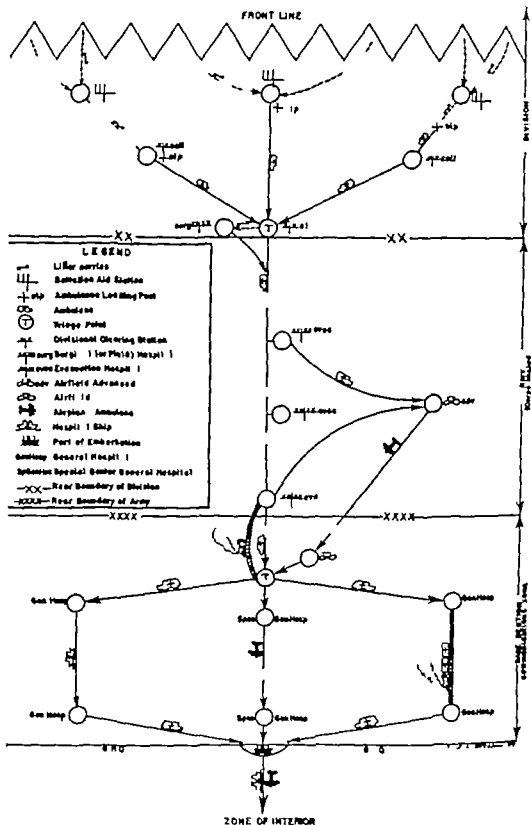

Fig. 1. Diagrammatic representation of an overseas theater (Courtesy of J. B. Lippincott Co.)

wound cultures are of no special value since many wounds have been found to heal by primary intention even in the presence of a profuse and varied flora. The most common cause of failure of secondary suture was due to infection caused by residual dead tissue. This may be detected at the first dressing by the discharge of pus and the inflammatory appearance of the wound margins.

Complicated wounds involving the soft parts and bony structures are the cause of the major part of reparative surgery. Compound fractures coming to base hospitals are removed from the transportation splints the wound is revised, and the fracture is reduced. In this group of patients the continuous penicillin therapy from the inception of wounding through to the evacuation to the base hospital has been of great value. Combined with whole-blood transfusions for anemia it has made possible reparative operations of the greatest magnitude and enabled the closure of original débridement incisions of compound fractures. Wounds of joints are treated by arthrotomy with the removal of devitalized cartilage and foreign bodies, after which the joint space is closed. In a severely traumatized joint, it may be even resected.

Massive organizing hemothorax is treated by thoracotomy, evacuation of the clot, and decortication of the lung. Post-traumatic empyema of the lung treated by surgery in combination with penicillin has resulted in rapid repair with full expansion of the lung. Advances in thoracic surgery have been such as to make possible the preservation of the maximum amount of lung tissue.

Skin grafts may be performed as early as the fourth day after injury. Primary suture of facial lacerations with splinting of the bony parts plus control of infection has resulted in a marked reduction of disfiguring mutilations. Early repair of intestinal fistulas and exteriorized segments of large bowel is performed at the base hospital with significant advantage. At this type of installation, cranio-cerebral wounds are closed and now even injuries of the peripheral nerve are repaired early.

Reparative surgery constitutes a new concept in military surgery. Just as the time-lag between wounding and initial surgery is related to the preservation of life and limb, so does the interval between initial and reparative surgery offer golden opportunities for adding to the preservation of life and limb.

BENJAMIN G. P. SHAPIROFF, M.D.

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

La Roa, E.: Breast Tissue as a New Source for Heterogenous Implants. *Am. J. Surg.* 1944 66 38.

Fresh and preserved breast tissues are used as implants in plastic work. The first breast tissue was secured from pendulous breasts. The donor patient and the recipient had the same blood grouping. The sedimentation rate, coagulation time and hemo-

globin were within normal limits. The erythrocytes, leucocytes and differential count were well within normal limits. The breast tissue upon removal was placed in a saline solution and kept warm.

Immediately after removal of the breast tissue the recipient patient was surgically prepared and the defect caused by an amputation for a scirrhus cancer was prepared for the transplant. The transplant was patterned to approximate a normal breast and was sutured into position. The temperature of the patient was slightly elevated following the operation. On the eighth postoperative day there was a bloody discharge from the breast dressings. The hospital stay was sixteen days. On the twenty-ninth day there was a recurrence of the sanguineous and fatty discharge. Four fifths of the original transplant remained. About sixty days postoperatively an additional sloughing occurred which lasted for ten days.

The breast tissue which was not used in this first operation was transferred to a sterile Tyrode solution and kept at a temperature of 45° F. Bacteriological tests were carried out periodically. On the seventh day portions of the preserved breast tissue were used in 3 operations. In the first, a portion was implanted in a defect of the forehead due to injury. This patient was discharged from the hospital on the third day. There was a primary healing on the seventh day. The end result, at three months appeared to be permanent.

In the second case a portion of the preserved breast tissue was implanted to correct a deformity of the nose. The end-result appears to be satisfactory.

The steps in the preservation of the tissue in Tyrode solution are enumerated. The Tyrode modification and the preservation of human tissue appear to be satisfactory.

RICHARD J. BENNETT, JR., M.D.

Harris, H. I.: Heterogenous Skin Grafts by the Coagulum-Contact Method. *Am. J. Surg.* 1944 65 315.

The author stimulated by the works of Sano reports the successful use of the coagulum-contact method for heterogenous skin grafts in 9 instances.

The histological changes on the application of a graft to the donor area are divided by Fomon into three stages: (1) the stage of plasmic circulation, (2) the stage of vascularization, and (3) the stage of organic union. The coagulum-contact method replaces the stages through which the tissue must pass in order to arrive at the same goal, and saves a period of from twenty-four to forty-eight hours. By the use of this contact method many hazards are eliminated. Shock is lessened by shortening the duration of the operative procedure and by lessening the quantity of anesthetic used.

The author paints the cell extract on the graft while it is still on the drum when the Padgett machines are used. In free hand grafts and in full thickness grafts the graft must be placed upon some material such as gauze. Complete hemostasis must be accomplished in all cases before the grafts are

applied. In redressing patients, the author uses a warm saline pack or compress for a few minutes before reapplying the dressing.

HAROLD C. OCHSNER, M D

Elman, R.: Acute Starvation Following Operation or Injury with Special Reference to Caloric and Protein Needs. *Ann. Surg.* 1944, 120, 350.

Six nutritional elements water salt, protein fat, carbohydrate and vitamins must be considered in discussing starvation.

In surgical practice measures are taken to prevent water and electrolyte starvation particularly by the simple injection of physiological saline solution. In addition most patients receive a certain amount of carbohydrate, sufficient at least to prevent ketosis although usually insufficient to meet all of the caloric needs. Vitamins, neglected for a great many years now are given adequately even if the patient is unable to take any by mouth. The remaining elements are fat and protein.

Deprivation of protein and caloric needs wholly or partially, although frequent, is, in general, viewed with complacency or considered inevitable. The supposition that tissue and other stores will supply safely the needs of the body has produced deleterious results. Wastage of body tissue, particularly tissue and plasma protein is not without untoward effects which begin almost at once after protein is removed from the diet.

When a healthy well nourished individual sustains a serious injury or undergoes a severe operation, starvation nearly always ensues. While the causes of such starvation are those which lead to deprivation of one or more of the nutritional elements, as a result of the injury there follows an unusually large breakdown of protein tissue, the toxic destruction of protein which leads to protein depletion even with the intake of a normal well balanced diet.

Even though the food requirements are normal and the patient is able to eat, the dietary intake after injury or operation is nearly always inadequate because of the starvation imposed by the surgeon who fears that the ingestion of food will prove deleterious. Often only fruit juices and broth are permitted such an intake leads to electrolyte or protein starvation or both. Excluding patients in whom it is necessary to keep the gastrointestinal tract at rest, as in general peritonitis, or in whom vomiting is present, such fear is usually without foundation. On the other hand when the patient cannot eat or is vomiting protein starvation will ensue because the usual parenteral injections contain only electrolytes and glucose.

Starvation in other patients may be due to partial or complete loss of appetite following the injury or operation aggravated often by overmedication particularly with morphine. Thus, there follows a failure in the normal impulses which ordinarily insure an adequate intake of food, and the patient left to his own resources does not eat, even when perfectly

adequate trays of food are served. Ordinarily anorexia ends quickly and spontaneously and the patient soon begins to eat of his own accord however, in many cases anorexia persists and becomes a manifestation of starvation itself. Thus a vicious cycle is established by which the very effect of starvation becomes a further cause.

The effects of acute starvation after injury or operation are

1. Loss of weight which, if water balance is maintained or its influence taken into account, means loss of body tissue but its physiological significance depends upon which of the two body tissues, fatty or protein, is depleted. Loss of protein tissue can be measured clinically by the amount of nitrogen excreted largely as urea and ammonia. Studies have shown that after injury or operation, as much as from 20 to 40 gm. of nitrogen may be excreted per day. By contrast, loss of fatty tissue, even if all of 2,000 calories were supplied by fat, would represent only 100 gm., or in terms of the tissue itself, 140 gm or one half pound, a day.

2. Asthenia. Most of the postoperative weakness or asthenia is attributed by surgeons to the operative procedure, but it may actually be due to starvation, particularly deprivation of protein. It has been shown that normal human beings who ingested a diet complete in all elements except protein developed after forty-eight hours severe symptoms of lassitude and asthenia, which were corrected rapidly by the ingestion of protein food. Elman has often observed that postoperative weakness was decreased by the intravenous injection of hydrolyzed protein. Jejunal alimentation beginning immediately after operation alleviates most of the asthenia symptoms and, in addition, accelerates convalescence.

3. Nutritional edema is an important serious clinical manifestation of starvation and may involve the gastrointestinal mucosa. Moreover it may be responsible for delay in wound healing, anuria, and even circulatory impairment. All of these complications may follow severe injury and operation, and, besides certain physical factors, hypoproteinemias long has been recognized as the most significant cause of nutritional edema.

4. Lowered resistance to infection is demonstrated by the fact that the production of antibodies is but from one-third to one-fifth as great in protein-deficient animals with hypoproteinemias as in animals on a regular diet, and it is probable that many postoperative infections may be due in part to a lowering of the immunological response of the body secondary to protein starvation.

5. Hypoproteinemias frequently occurs after operation or injury. Although published data on the extent vary considerably hypoproteinemias frequently escapes detection because its existence is masked by two factors (1) the albumin fraction which is obscured by an increase in the globulin fraction due to the infection and (2) dehydration, which is responsible for a normal concentration of both fractions, although the total circulating protein is depleted.

6. Death That a fatal outcome after injury or operation may be due to starvation is an inescapable conclusion in several instances. Extreme emaciation is always the prominent finding at postmortem examination.

Treatment of starvation is simple, consisting merely of overcoming the patient's loss of appetite with adequate food intake, looking to the palatability of the food and avoiding idiosyncrasies making judicious use of sedation and giving a diet complete particularly in adequate protein.

Three glasses of a drink made by stirring 100 gm of skimmed milk powder into 200 cc. of water furnished 34 gm. of protein and 52 gm. of carbohydrate. These amounts exceed those in a quart of milk with only one fifth of its volume, and will meet the daily protein needs of a normal-sized adult. Solid food such as eggs and meat should be added as soon as possible. If necessary parenteral or tube feeding after operation or injury may be employed. The bulk problem can be made easier by sacrificing some and perhaps even a considerable part of the caloric requirements.

Evidence indicates that a large part of the caloric needs may safely be sacrificed for short periods with out physiological impairment provided an adequate protein intake is assured.

It may be more important to insure nitrogen balance with a high protein diet than to provide fat and carbohydrate for all the caloric needs. Should loss of body weight occur as a result of starvation it is much more important that nonessential tissue fat rather than essential tissue and plasma protein be depleted.

Starvation may be avoided to a considerable extent by recognizing anorexia as a therapeutic challenge rather than an inevitable symptom. Because prevention of starvation is much easier than its cure adequate nutrition should begin immediately after injury or operation. STEPHEN A. ZICKMAN M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Orr Ewing, J. Scott J. C. Maalaa, F. H. Trueta, J., and Gardner, A. D.: Local Sulfanilamide Treatment of Fresh Wounds In Complete Plasters. *Brit J Surg* 1944 32 83

This investigation was aimed at obtaining incontrovertible evidence about the effect of local application of sulfanilamide on the bacteriological condition of compound fractures and other severe wounds treated by thorough cleaning, excision and enclosure in plaster and at correlating this evidence with the clinical results. The authors treated a series of cases with and without the local application of sulfanilamide, attempting to avoid any selection that might vitiate their conclusions.

They demonstrated a selective reduction of the wound flora by sulfanilamide but did not establish a corresponding clinical effect.

HOWARD A. MCKNIGHT M.D.

Connor G. J. and Harvey S. C. The Healing of Deep Thermal Burns. A Preliminary Report. *Ann Surg* 1944 120 362

The chief cause of delay in the healing of deep thermal burns is the continued presence of the slough. Dead tissue is essentially powerless to combat infection as long as it is present. Successful skin grafting is impossible, and contracture continues hence the advantage of removal is fully realized.

Enzymatic digestion of slough in wounds has been tried with a proteolytic compound containing papain, urea and caroid in a saturated aqueous solution and various other enzymatic compounds. Several of these however damage living tissue.

The hydrogen ion concentration of the wound fluid is increased in many infected wounds and preliminary experiments with local application of various organic and inorganic acids revealed that the separation of the slough could be greatly hastened if the pH of the surface of the wound was sufficiently lowered. Of the large series of acids studied pyruvic acid presented outstanding advantages. With it the necessary balance between the pH and concentration of the acid can be obtained in order to accomplish the desired results.

Deep burns produced on dogs by the direct application of a low blue gas flame to the skin for twenty seconds over the dorsolateral aspect of the trunk resulted in a standard burn from 3 to 4 cm. in diameter and uniformly involved the full thickness of the skin.

The experimental wounds were dressed within a few hours after burning with a thick layer of paste consisting of a solution of pyruvic acid at a pH of 1.0 and of 8 per cent cornstarch.

The control wounds were dressed within a few hours after burning with either dry gauze, vaselined gauze or a paste consisting of 8 per cent cornstarch in distilled water.

In the experimental series the slough separated completely within seventy two hours whereas in the control group the complete separation of the slough required from ten to twelve days. The slough softens on its surface and breaks up into many pieces which are firmly adherent. During the week before complete separation the wound is covered with a necrotic, stringy adherent layer.

The separation of the slough in the experimental group however appears to begin at the periphery where, in twenty four to thirty-six hours there is slight softening. A plane of cleavage develops beneath the otherwise intact slough and separation proceeds centralward. After forty-eight hours the cleavage has developed to the point where the slough, aside from soft dermal tags at the periphery is either completely free or loosely attached beneath its center. In another twelve to twenty four hours separation is complete with the slough lying free in one piece.

There is no evidence of digestion of the slough itself and the skin adjacent to the burn appears undamaged.

Grossly, the resultant base is pink subcutaneous tissue. Within seventy-two hours after burning this base is unusually vascular and, histologically exhibits evidence of early granulation tissue. The edges of the wound are sharp and clean and are often tangential as would be consistent with the more superficial damage at the very margins. The pink clean base evident after separation of the slough accepts a split graft of skin immediately. This regularly takes, and all or part of the wound may be successfully treated in this manner.

The problem of infection is thus resolved and the full objective of treatment achieved, even before the slough in the comparable control wound has completely separated.

The use of this method on man is being studied but has not as yet been adequately tested, nor has a standardized procedure in all details been adopted. Until these have been done, application of the method for the purposes of treatment should be delayed.

STEPHEN A. ZIDMAN, M.D.

McClure, R. D., Lam, C. R., and Romance II.: Tannic Acid and the Treatment of Burns. *An Obsequy Ann. Surg.* 1944, 80: 387.

Twenty years ago the tannic acid therapy of burns was begun at the Henry Ford Hospital. The authors of this article hope that this communication from a group working in the same institution will result in the abandonment of this type of treatment of burns and related methods. This unqualified recommendation is prompted by comparatively recent clinical experience and animal experiments by the authors and others. Under certain circumstances the use of tannic acid produces a severe if not a fatal lesion in the liver and carefully controlled experiments have shown that it moderately inhibits wound healing.

Four illustrative cases are reviewed. Two cases were treated with tannic acid and 2 were treated with presumably inert vaseline dressings. Liver necrosis and jaundice were present only in the tanned cases.

The authors raise the questions: If tannic acid is toxic to the liver and does local damage, why was it used for 20 years and why was it adopted so enthusiastically almost all over the world? What about the much publicized mortality rate reductions? We fear that the largest factor was wishful thinking.

Liver necrosis has been reported in a considerable number of burned patients treated with tannic acid. Nonfatal cases frequently show marked disturbance of liver function in the acute phase of the burn. The liver lesion is easily reproduced experimentally. Wound healing experiments on animals and on human donor sites indicate that tannic acid retards healing considerably.

JOSEPH GARTER, M.D.

Jackson, A. V.: Liver Necrosis in Burns Treated with Tannic Acid. *Med. J. Australia* 1944, 352.

Since the outbreak of war the tannic-acid method of treatment of burns has been criticized from sev-

eral points of view. It appears to be unsuitable for certain areas, such as the face and hands, because the rigid eschar is sometimes followed by ischemia. Also trouble is sometimes caused by sepsis hidden under the eschar. Of even more serious import is the suggestion, first made in 1943 by Wells, Humphrey and Coll, that tannic acid may cause liver necrosis.

It appears from the review of the literature that pronounced liver necrosis is common in patients who die from burns treated with tannic acid, and is slight or absent from those not so treated. However, the two groups—the tannic-acid group and the nontannic-acid group—are not quite comparable. Nearly all the patients not treated with tannic acid died before 1935 so that not only did they not have tannic acid treatment, but they also did not have the benefit of modern ideas regarding the importance of hemoconcentration in burns and its control by intravenous serum therapy nor were modern chemotherapeutic agents for the control of sepsis available. Consequently, the older patients frequently died in the first three days from septicemia, or after the eleventh day from sepsis.

In spite of the accumulating evidence to the contrary, therefore, it still remains a possibility that the failure to observe liver necrosis in patients who were not treated with tannic acid may have been due to the fact that most of these patients died (1) before liver necrosis (caused for sake of argument, by some hypothetical burn toxin) and not by tannic acid had time to develop (2) later from septic infection of a burn not sufficiently large to cause much toxemia or (3) perhaps after liver repair had been effected.

The need of further evidence of the toxicity of tannic acid in human beings prompted the author to examine the livers of 8 patients who died from burns. All patients, except 1, died between the third and eleventh days. In the livers from 3 patients treated with tannic acid and silver nitrate, extensive hepatic necrosis was found. In the livers from patients whose burns were not treated by tanning, cloudy swelling was the only abnormality found.

JOSEPH K. NALAT, M.D.

Osborne, R. P.: The Treatment of Burns and Wounds with Skin Loss by the Envelope Method. *Brit. J. Surg.* 1944, 3: 24.

Thirty-one cases of burns were treated during a nine-month period. Six were recent burns, 13 on unhealed wounds and 12 were old burns.

Envelopes of the Bunyan-Stannard type were used, the envelopes being sterilized previous to use.

An anesthetic usually is given with the application of the first envelope. Application of the envelope consists of arranging a rubber sheet beneath the area to be treated so that the overflow runs into a receptacle. Previous dressings are removed, the wound photographed, and a smear taken for bacteriological examination. An irrigation with 1 per cent sodium hypochlorite at 110 degrees is carried out and the

the sterilized envelope is applied. The same solution is used for irrigation through the envelope. Five pints are used for an extremity. The envelope is allowed to drain for from five to ten minutes, then the interior is dried by air blown through with an electric hair dryer. Subsequent irrigations are carried out three or four times a day. Irrigation is ordinarily painless. When a smarting sensation is reduced the concentration of the solution is reduced.

Dermatitis in the form of furunculosis may be seen on undamaged skin within the envelope after two or three days; possibly it is due to insufficient drying.

Excess granulations are controlled by pressure dressings. Spints may be applied outside of the envelope if necessary. Active movements are carried out from the start. Delayed healing occasionally occurs but is accelerated by the removal of the envelope. The life of an envelope is usually from three to five weeks. Sometimes the regenerated epithelium is quite fragile and it is necessary to do a skin grafting. Skin grafting of the Thiersch type may be carried out safely after hemolytic streptococci have been eliminated; this being determined by three successive negative reports. Grafts are applied in sheets or the chessboard variety is used. The chessboard type is obtained by cutting the skin in $\frac{1}{4}$ inch squares. These $\frac{1}{4}$ inch squares are then applied to make the chessboard pattern. The envelope and a pressure dressing are then applied. Pressure dressings are removed on the third day. Irrigation (1 to 20) is carried out twice daily. There are no dressings after the seventh day.

Several of the cases are discussed in detail as to the condition on admission, treatment and bacteriology. The improvement of the patients' condition and the maintenance of full function in every case is very noteworthy. Risk of infection and crossinfection are avoided by this method.

When bacteriological examination showed the presence of the hemolytic streptococcus at the time of the application of the envelope, all of these organisms disappeared although in some cases sulfanilamide was required.

No cases of deformity occurred when the envelope method of treatment was used.

RICHARD J. BENNETT, JR.

Clarkson, P.: Late Closure of Wounds. *Lancet* Lond. 1944, 247, 395.

Late wounds are best closed by a radical attack which, by excision of granulations, the fibrotic base, and the new skin back to good surgical material, aims at reconstitution of the original defect in a clean field. This defect is then closed at the same operation.

Closure of the local tissue is possible in most of these wounds and closure in as straight a line as possible gives the best functional results and earliest sound healing.

Direct approximation and secondary suture, after wide undermining is the most widely applicable

method (40 per cent in this series) but more distant tissue may be made available by transferring it over the defect on a swing or rotation flap in a good percentage of cases (33 per cent of this series).

The upper limit of these local closures in the trunk, and proximal parts of the limbs lies between 80 and 100 sq. cm. and depends on the site of the defect. Defects of 80 sq. cm. in the elbow or upper regions of the calf can be closed by local tissue with rotation flaps and abdominal and flank tissue up to 200 sq. cm. can be made available for trunk defects.

There is no contraindication to a free graft if it will take but earlier and sounder healing is obtained when local tissue can be made to close the wound. A wound more than from six to eight weeks old does not offer a good prospect for 100 per cent take and sound healing of the graft. A free graft is nearly always necessary at least in part, for defects of more than 120 sq. cm. In such large defects the free graft can often with advantage be combined with a local flap to provide both a skin and fat cover for special parts of the wound.

With increasing use of delayed primary suture and early secondary suture, combined with local penicillin, the percentage of wounds needing late closure may be expected to decline sharply.

Soft tissue wounds however extensive should all be soundly healed within six weeks of the injury. The surgeon must be able to achieve this for his cases or else should send them early to a center equipped to do so.

JOHN J. MALONEY, M.D.

Lockwood, J. S., White, W. L. and Murphy, F. D.: The Use of Penicillin in Surgical Infections. *Ann. Surg.* 1944, 120, 311.

This article presents the experiences and results of penicillin therapy in surgical infections. It portrays what has been learned by one of the participating groups of investigators working under the program of the Subcommittee on Infected Wounds and Burns of the National Research Council regarding the scope and limitation of penicillin in surgical infections. It brings out moreover the extent to which penicillin gives promise of meeting some important deficiencies of the sulfonamides through its effectiveness in the presence of pus, its powerful action against staphylococci, and its lack of toxicity.

A brief review of the history of penicillin and its properties as a chemotherapeutic agent is given. The organisms against which it is effective and those which are resistant are enumerated.

The local use of penicillin either by itself or in conjunction with systemic therapy has given results which are highly encouraging. Emphasis is properly placed on the necessity for careful bacteriological study of every case in which the drug is used in order to determine whether or not the causative organism is susceptible or whether resistant strains of staphylococci or streptococci will be encountered which will require more intensive treatment.

Within eighteen months about 440 patients have been treated. The diseases encountered were of

many varieties, both medical and surgical, and except for special research cases of chronic osteomyelitis and pulmonary suppuration all of the patients were critically ill. Moreover most of them had received intensive sulfonamide treatment without success for periods of from two days to several weeks.

Four main groups of cases are discussed: acute disseminated sepsis, and localized infections of the serous cavities, soft tissues and bone respectively.

1. Among the cases of acute disseminated sepsis (bacteria and meningitis) there were 57 patients with staphylococcal bacteremia, two-thirds of whom survived; 15 with streptococcal bacteremia and 50 with suppurative meningitis; 43 pneumococcal and 5 staphylococcal. The patients with staphylococcal bacteremia probably illustrate better than any others the important position of penicillin as a chemotherapeutic agent. Whenever possible they were treated by the continuous intravenous drip method and received doses of from 60,000 to 150,000 units in each twenty four hour period. With impressive regularity these patients tended to show improvement within forty-eight hours and unless complications had developed, were clinically recovered from the acute disease within three to seven days. The complication most likely to interfere with successful treatment was vegetative endocarditis which developed in 10 cases. In most of these cases of bacteremia no resort was made to surgical treatment of the foci of infection during the acute septic phase, because in the face of progressive improvement in the patient's condition it seemed wise to defer operative procedures until a time of election. In several instances the foci subsided without drainage, particularly those developing in well vascularized tissues about the face and in the lung. When localization occurred in bone it was usually necessary to resort to surgical drainage ultimately.

Cases of meningitis, with or without bacteremia, particularly those due to staphylococci, have responded promptly at times even without intrathecal treatment but in pneumococcal meningitis a daily injection of about 10,000 units of penicillin into the lumbar spinal canal, cisterna, or ventricles is imperative and recent experiences suggest that the cisterna objections are particularly advantageous in severe infections. In meningitis it remains a matter of great importance to explore potentially infected mastoids when a prompt clinical response is not forthcoming.

2. Under localized infection in serous cavities are discussed empyema, suppurative arthritis, and peritonitis. When empyema is due to an infection with a penicillin-sensitive pneumococcus, staphylococcus, or streptococcus in pure culture and treatment is instituted within the first few weeks it is possible to bring about sterilization of the cavity and ultimate cure, without resort to thoracotomy drainage. Frequent aspiration of the cavity and injection of from 10,000 to 25,000 units of the drug rapidly brings about sterilization of the cavity.

In the acutely ill, systemic treatment in combination with local injection is given.

Complete restoration of function has occurred in staphylococcal arthritis, and in cases of primary peritonitis from hemolytic streptococci or pneumococci the infection would be expected to respond favorably to penicillin treatment. Less certain, however, would be the results of treatment of infection developing after appendicitis, including pyelitis and perihaptic infection.

3. Under "localized infections in soft tissues" are discussed such topics as cellulitis of the face and orbit, boils and carbuncles, and pulmonary suppuration. Particularly striking have been the results of treatment in patients with cellulitis of the face and periorbital tissues. The recuperative power of these well vascularized areas is illustrated by the frequency with which penicillin treatment has been sufficiently effective to prevent suppuration in case of facial cellulitis.

There is every reason to believe that the management of boils and carbuncles will be improved by combining penicillin therapy with surgical removal of devitalized skin, fat, and fascia. The spread of cellulitis and localization of the suppurative focus usually occurs within two or three days after systemic therapy is started.

The treatment of patients with chronic post-lung abscesses has not yielded striking results, perhaps because many of the bacteria in these lesions are resistant to penicillin. The most that can be reasonably expected of the drug in these cases is to improve the condition of the patient for operation and to reduce the incidence of postoperative infection of the pleural cavity.

Penicillin cannot be expected to have a lasting curative effect in chronic bronchiectasis, but it can be used as a means of preparing septic cases for surgical treatment.

4. In cases of acute hematogenous osteomyelitis of the long bones with or without bacteremia, penicillin therapy will usually bring about rapid disappearance of evidence of disseminated sepsis, and usually there is a fairly prompt regression of the signs and symptoms of local inflammation at the site of localization.

The administration of penicillin to patients with chronically draining sinuses harboring staphylococci or streptococci will usually bring about a marked reduction in numbers or even disappearance of these organisms in the exudate, but direct culture of curettings from these sinuses may reveal persistent organisms not apparent on an ordinary swab culture. If no sequestrum is apparent roentgenographically the sinus may even become completely healed during the course of two or three weeks of treatment.

It was concluded that when penicillin, as administered systematically, it modified the course of most infections in which the causative organism was sensitive to penicillin in vitro.

Dramatic curative responses in disseminated sepsis were observed, particularly when the circulation to the localized distributing foci was adequate to effect a contact between the drug and the bacteria.

such cases surgical treatment which would have seemed unavoidable in the past, could be postponed or avoided altogether by the use of penicillin.

Favorable responses characterized by subsidence of toxemia, correction of anemia, rapid healing of infected or seriously contaminated wounds and elimination of infection within the pleural cavity or joints occur as well as failures. The latter occur particularly when the organism is insensitive or when the lesion under treatment is attributable only in part (or not at all) to the persistent activity of penicillin-sensitive bacteria, and under conditions in which penicillin cannot be brought to the infected area because of poor circulation or limited transport of the drug.

Careful bacteriological studies are essential if penicillin is to be used with maximal effectiveness.

STEPHEN A. ZIDMAN, M.D.

Bigger J. W.: Inactivation of Penicillin by Serum. *Lancet* Lond. 1944, 247-400.

Penicillin is inactivated by contact with human serum or blood. The degree of inactivation varies greatly with different specimens of serum and is much greater at body temperature than at lower temperatures.

This inactivation may lead to underestimation of the amount of penicillin in a patient's serum. Inactivation *in vivo* is probably important chiefly in cases in which the excretion of penicillin by the kidneys is slow.

JOHN J. MALONEY, M.D.

ANESTHESIA

Whalen E. J.: Anesthesia in Peroral Endoscopy. *Ann. Otol. Rhinol.* 1944, 53-469.

This article reviews anesthesia in peroral endoscopy. The endoscopic examination is not always possible under local anesthesia and general anesthetic methods are sometimes necessary.

It is suggested that all cases be individualized as to preanesthetic preparation and selection of type of anesthesia. The purposes of preanesthetic medication are elucidated and such drugs as pentobarbital sodium, morphine and scopolamine are discussed. In practice the ideal state of tranquility is effected by the use of morphine sulfate (gr. $\frac{1}{4}$) and scopolamine (gr. $\frac{1}{100}$). If these are given to an adult one hour before the administration of cocaine anesthesia for peroral endoscopy the patient will be quiet and co-operative and the amount of cocaine necessary to produce satisfactory anesthesia will be reduced to a minimum. When morphine and scopolamine are to be used a 1:25 ratio is maintained. The preanesthetic preparation of the patient with proper selection of the preliminary medication is of the utmost importance whether the basic anesthesia is of the local or general type.

Cocaine in 5 per cent strength has been found very satisfactory for the endoscopic procedures, the technique of using it is described in detail. The general inhalational anesthetic agents are discussed. Pen-

total has been found to be an anesthetic of high value when a general anesthetic is indicated. The disadvantages which are connected with its use can be anticipated and partly overcome. The administration of morphine and atropine one hour before the induction and the spraying of the pharynx and the larynx with cocaine hydrochloride (5 per cent solution) are methods used to prevent laryngospasm. Curare is a recent addition to the endoscopist's armamentarium, producing muscular relaxation in these cases of muscular spasm. Avertin is used infrequently because of its respiratory depression and the slow return of reflexes after its use.

Apomorphine (gr. $\frac{1}{40}$) is suggested as a counteractant of the ill effects of scopolamine overdose. Morphine has been discontinued in children and infants because of a few unfortunate experiences. The need for a clear airway is stressed. The respiratory depression which may occur during pentothal anesthesia must be treated by the establishment of a patent airway and inflation and aeration of the lungs.

Infants do not require anesthesia and preanesthetic medication for any endoscopic examination or operation. Children from three to fifteen years require general narcosis. This is best obtained with ether usually given by the open drip method. A small dose of atropine (gr. $\frac{1}{200}$ for the child of ten gr. $\frac{1}{300}$ for the child of five) is good premedication.

MARY KARP, M.D.

Buch I. M., Newton L., and Posner A. C.: Continuous Caudal Analgesia in Obstetrics. *Am. J. Surg.* 1944, 66-68.

One hundred and thirty cases of caudal-block anesthesia were reported by the authors in 50 cases single injections were made. The first 15 patients received 2 per cent procaine and the last 15 received 1.5 per cent metycaine. Continuous drip infusion was preferred because, once set up, it is automatic; it requires less unusual equipment than other methods and the obstetrician can visit the patient at his own convenience rather than at specific intervals as is required when other methods are used. A 19 G needle of $\frac{3}{4}$ inch length was used for the initial injection. After the test-dose period the needle was replaced by a 23 G needle through which a No. 5 ureteral catheter was threaded. The catheter was then hooked up to a graduated container connected by means of a Murphy drip chamber. The rate of flow usually required was about 12 drips a minute of 2 per cent procaine or 1.5 per cent metycaine.

Seventy-three of the patients were primiparas and 57 were multiparas. The amount of 2 per cent procaine required for a full initial effect was from 40 to 50 cc. and the amount of metycaine usually needed was from 30 to 35 cc. Two postpartum abdominal sterilizations proved refractory as to the height of the anesthesia. Caudal block has been discarded by the authors as being too unreliable for abdominal surgery because of the time factor and the occasional refractory cases.

The full effect of anesthesia from the initial dose was usually reached within fifteen or twenty minutes. The average duration of labor from the onset of the caudal block was three hours and fourteen minutes, the longest labor being eight and one-half hours.

Continuous caudal block had no effect on the duration intensity or frequency of uterine contractions but it had a relaxing effect on the cervix. After the discontinuation of the drip or after a single injection, analgesia lasted an average period of one hour and twenty four minutes.

Motor paralysis of the legs was more frequent among the patients who had had continuous caudal block of long duration. In only 1 instance was the drip discontinued because of a marked fall in blood pressure.

Complications were few: excitement and disorientation occurred in 9 cases, chills in 4, burning in 5, nausea and vomiting in 3, dizziness in 3, nonuterine pain in 10, uncontrollable desire to defecate in 1, and unilateral anesthesia of the perineum in 1.

The mechanism of caudal anesthesia was discussed. Absorption begins immediately and goes on continuously and its rate is never constant. A fair amount of procaine must be absorbed without entering into protoplasmic combination to produce anesthesia, and without even serving the usual function of maintaining that combination. If procaine is injected as soon as the caudal effect begins to wear off only a small amount is necessary to maintain the anesthetic level. If this level is allowed to fall, however, the amount of free procaine will fall considerably below the critical level in a large region, and considerably below the desired upper level. To regain the original level of anesthesia will now be a much more difficult problem.

The results in 97 cases were wholly successful. In 19 cases the block, though effective, was discontinued before delivery, and in 14 cases there was complete or partial failure or the dura was penetrated. Thirteen cases were refractory, that is the usual initial dose produced only a partial effect. In these cases small doses were injected at intervals until complete analgesia was obtained. Temporary motor paralysis of the lower extremities was noted in 13 cases.

Among the 49 patients in whom the blood pressure was carefully watched, 31 showed some depression. In 18 patients the systolic fall was at least 20 points. There were 3 fetal deaths in the series.

In conclusion, the author believes that confidence should be maintained in the method. In its present state, however, the inherent disadvantages obviate its universal use and thus preclude its acceptance as the long awaited panacea.

MARY KARP, M.D.

Williams, D., and Sweet, W. H. The Constitutional Factor in Anesthetic Convulsions. *Lancet*, Lond., 1944, 247, 430.

The purpose of this article is to report the results of electroencephalographic investigations of a series

of cases of anesthetic convulsions and to discuss the significance of the results obtained.

Of 42 patients with anesthetic convulsions, 40 had either the majority with nitrous oxide and oxygen, 11 had inductions with ethyl chloride, 1 had pentothal, and 1, divinyl ether. Electroencephalography was carried out on 22 of the patients, 13 of whom were males, 5 were children. Only 1 third had had acute inflammatory disorders requiring surgical intervention. The majority were "clean" cases and had a normal temperature at the time of operation. All anesthetics had been administered by experienced anesthetists and in every case the diagnosis of anesthetic convulsion was certain.

Abnormal electroencephalographic records were obtained from about three-fourths of these cases. Paroxysmal outbursts of abnormal cause were seen in more than half and larval epileptic headaches in a fourth of them.

The incidence and nature of the different abnormal discharges seen were identical with those found in idiopathic epileptics.

All the evidence presented supports the view that anesthetic convulsions are primarily due to a subnormal but latent epileptic liability. Factors which arise during anesthesia were mainly the precipitants of the convulsion.

Thompson, G. N., McGinnis, J. E., Van Harreld, A., Wierama, C. A. G., and Thet, E. R.: Electrocortical. Clinical Comparison with Electroshock. *War Med.*, Chic., 1944, 6, 53.

Electrocortical has been used as an anesthetic agent for animals. A clinical examination of the method in the treatment of schizophrenia was made in a study of 50 patients and the results were compared with those in a similar series of cases of patients treated by electroshock and by insulin. The conclusion was that electrocortical is superior to electroshock for schizophrenia, and is similar to insulin in its efficacy in the treatment of the disorder.

The standardized electrocortical technique is described in detail. A current of from 160 to 190 ma. was applied through electrodes bitemporally placed and was maintained for thirty seconds at the end of this time the currents were dropped to between 60 and 75 ma. At the end of from sixty to seventy five seconds, the current was raised at the rate of 5 ma. every fifteen seconds to a maximum of 125 ma. at five minutes. The treatment was usually terminated at seven minutes.

Certain neurological signs were seen constantly during the narcotic state produced by electrocortical. These were described and compared with electroshock.

In all three groups of patients studied, there was an initial cardiac arrest which usually lasted from three to seven seconds. In electroshock the tachycardia began shortly after the clonic phase, or about twenty seconds, and return to normal occurred usually within a few minutes. During the

entire duration of the current in the electroneurosis, the tachycardia continued and sometimes increased to rates of between 140 and 160 or sometimes even higher.

The principal difference was a prolongation of the stimulation of the autonomic nervous system but other phenomena not observed in electroshock were observed such as prolonged flexor tone and forced grasp. During deep insulin coma autonomic phenomena such as flexor tone and forced grasping were similarly present. The reactions of the patient during the postconvulsive phase of electroneurosis resembled those observed during insulin coma. It is believed that in its present status electroneurosis is not practical as an anesthetic device for human beings.

SURGICAL INSTRUMENTS AND APPARATUS

Frantz, V. K., Clarke, H. T. and Lattes, R.: Hemostasis with Absorbable Gauze (Oxidized Cellulose). *Ann Surg* 1944, 120: 181.

A series of experiments were undertaken to reproduce as nearly as possible lacerated bleeding wounds such as those which in clinical practice might necessitate gauze packing. No adjuvant to promote clotting was used and no immediate effect was expected other than cessation of bleeding inherently due to the presence of the absorbable packing. These observations are based on experiments in which the wounds were made with the animals under general anesthesia, and with aseptic precautions.

The oxidized gauze was easier to pack into a bleeding wound than ordinary gauze. It seemed more pliable and when wet with blood slightly sticky. The oxidized gauze used dry was observed to swell when saturated, easily filling all the irregular crevices in the wound. The combination of blood and

oxidized gauze resulted almost immediately in a dark brown or black mass and as soon as this discoloration occurred bleeding usually ceased. The hemostatic effect appeared to depend not on clotting within the meshes of the gauze but on the swelling of the material and its sticky character when blood soaked so that the packing itself took the place of clot.

The authors have not studied any possible direct effect on the clotting process. Neutralization of the material with calcium acetate resulted in the loss of the described properties and rendered it less effective as a hemostatic. As early as twenty-four hours after packing the oxidized gauze was so friable that it broke when an attempt was made to withdraw it in contrast to ordinary gauze which could be withdrawn but which in clean wounds, especially was usually stuck, so that force was necessary for withdrawal. With ordinary gauze removal was apt to be followed by bleeding, which sometimes required secondary packing. With oxidized gauze in an open wound for forty-eight hours the gelatinous mass of brown material which represented the blood-soaked packing could be gently scraped away from the wound surface without renewal of the bleeding. Oxidized gauze even when not absorbed early was not invaded by reparative tissue. The foreign body therefore was not incorporated in scar to any extent and scarring was minimal. The absorbable gauze has also been used for hemostasis in 17 clinical cases.

This material even though soluble and relatively non-irritating is a foreign body in the tissues and remains as such often for several days. It should be used at least in wounds which are closed without drainage in as small quantity as possible. It is not a substitute for meticulous surgery and surgical principles must not be violated in its use.

LOUIS T. BYARS, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Rendich R. A. and Harrington L. A.: Roentgenologic Observations in Mesenteric Thrombosis. *Am J Roentg* 1944, 5 37

Although mesenteric thrombosis as a clinical entity has been recognized for over one hundred years very little attention has been given to the radiological diagnostic aspects of the disease.

The authors found one striking common finding in 3 cases. The KUB film of the abdomen revealed a distention of the intestinal loops and right half of the colon simulating a mechanical block. Gas collection ended abruptly at the splenic flexure. Gas distribution in the distended bowel corresponded to the distribution of the superior mesenteric vessels. The authors were somewhat surprised to find that no mechanical block existed when the patient was examined after he had been given a barium enema. This they have called a sign-complex that is the KUB film indicates mechanical intestinal obstruction whereas the barium enema reveals a colon filled with barium and no evidence of a block.

Three cases of mesenteric thrombosis are reported in which roentgenograms revealed distention of the intestines and right half of the colon corresponding to the superior mesenteric artery. It is the opinion of the authors that an early diagnosis aided by the roentgen findings offers an excellent opportunity for bowel resection and eventual recovery.

MAURICE D. SACIS, M.D.

Sahler O. D. and Hampton A. O.: The Roentgen Appearance of Common-Duct Stones. *Am J Roentg* 1944, 5 298.

Common-duct stones can often be demonstrated on plain abdominal roentgenograms or spot roentgenograms of the bile-duct area. They should be suspected in any case in which calcification is seen in the region of the gall bladder or common duct, in which calcium bile milk is demonstrated or in which the patient is jaundiced. The fact that common-duct stones can be seen on the plain roentgenogram is not generally appreciated. This is probably due to two factors: the relative infrequency of common-duct stones and the difficulty in demonstrating their location accurately.

Diagnosis of common-duct stones from the plain roentgenogram is dependent upon the presence of sufficient calcification to give a positive shadow. At the Massachusetts General Hospital, Boston, about 3 cases of easily demonstrable common-duct stones are seen per year at the present time.

The chief difficulty in the diagnosis of the common-duct stone without a contrast substance lies in establishing the correct location. The differentiation of common-duct stone from renal or cystic stone is the first problem to be solved. Since a stone in the cystic

duct may lead to hydrops of the gall bladder, while one in the common duct would not do so, the finding of a mass in the gall-bladder region associated with calculus is indicative of a cystic-duct stone. The cystic-duct stone may however not necessarily cause hydrops. If in the anteroposterior projection, a stone is seen to lie in the region of the duodenum or duodenal loop, the conclusion that it is in the common duct is justifiable since it will be below the juncture of the cystic and common ducts. In a rare case in which a dye study of the gall bladder has been made in addition to the plain roentgenogram, a diseased gall bladder may be found which retains its power of concentrating dye and subsequently contracts after a fatty meal. In such an instance, however, the bile duct would probably be outlined by dye and stones could still be accurately located.

HAROLD C. OGDEN, M.D.

Kenny M.: The Clinically Suspect Pelvis and Its Roentgenographic Investigation in 1000 Cases. *J Obst Gyn Brit Empire* 1944, 51 277

Roentgenographic examination was made in late pregnancy in 1,000 women. The objective of the survey was to determine whether or not roentgenograms could be of aid in those cases in which a previous history of abnormal labor or the clinical examination caused the physician to fear abnormal delivery.

The following types of conditions were investigated: (1) clinical pelvic contraction, (2) cephalopelvic disproportion, (3) fetal malpresentation, (4) clinical evidence of bone pathology, and (5) cases who had had a previous prolonged labor.

Before the beginning of the present work conflict, a combination of Thomas Caldwell-Moloy Roberts, and Rowden methods was used. As films became scarce and the diagnostic ability of the author improved a single anteroposterior film of the pelvis or even a lateral view would suffice. In all cases, an attempt was made to forecast labor. With increased experience the incidence of error in roentgenographic forecasts was low.

The Caldwell-Moloy classification of pelvis was used that is: gynecoid, android anthropoid or platycoeloid and platypelloid. Of the 1,000 cases examined, more than 900 belonged to the gynecoid, android or some combination of these types. 64 were anthropoid (platycoeloid), 18 platypelloid, and 6 pathological. A marked conformity was found between the physical form and the pelvic type. In 533 cases, the physical appearance and pelvic type conformed. 8.6 per cent (38 cases) anthropoid type, 7.8 per cent (118 cases) android type, 67.7 per cent (733 cases) gynecoid type. There were 106 cases in the anthropoid group and 43 in the gynecoid group.

A history was available in 540 of the 1,000 cases. Toxemias of pregnancy were in mild or severe form:

they occurred in 8 per cent of the gynecooid type, 10.9 per cent of the gynecoandroid, 78.5 per cent of the android, 57.7 per cent of the androgynecooid, 5.1 per cent of the anthropoid, and 12.7 per cent of the platypelloid. Puerperal morbidity was 23.9 per 1,000 cases and was higher in the android group.

As a result of the study the author believes that external antenatal measurements are negligible. There is no constant relationship between external and roentgenographic measurements. In pelviroentgenographic interpretation attention is given to the conformation of the sacrum and the posterior sagittal diameter of the midpelvis. During the six years in which this study was made, 10,197 women were delivered and roentgenographs were taken in 1,000 suspected cases. Of the 178 cesarean sections, 145 were done in the suspected group. Three hundred and seven of 342 forceps deliveries were done in the suspected group also. The gynecooid and android pelvis showed the lowest mortality rate. The author believes that routine pelvic roentgenographic measurements are essential, especially in the primigravida, and that undoubtedly they would help reduce untimely and ill-advised surgical procedures.

MAURICE D. SACHS, M.D.

Epstein B. S., and Davidoff L. M.: Iodized Oil Myelography of the Cervical Spine. *Am. J. Roentg.*, 1944, 52, 253.

The authors had the opportunity to study clinically and by means of iodized-oil myelography 5 cases of rupture of the nucleus pulposus of the lower cervical spine. There were 76 cases in the entire series of ruptured intervertebral discs, the remaining 71 occurring in the lower lumbar spine.

The myelography was performed by the lumbar route. With care it was possible to prevent entrance of the iodized oil into the cranial cavity, but when the oil did enter no difficulty was encountered in returning it to the spinal canal after the patient was placed in the upright position.

The detailed technique was as follows:

From 1.5 to 2 cc. of pantopaque or lipiodol were instilled into the lumbar subarachnoid space; then the patient was placed securely face down on a motor-driven tilt table equipped with a device for spot film roentgenography and the table was tilted according to the requirements of the fluoroscopic observations. As a rule it was necessary to invert the patient to an angle of from 70 to 85 degrees for the oil to enter the upper thoracic and lower cervical regions. If the oil passed too rapidly the table was returned promptly to the horizontal position until the proper rate of flow was obtained without entrance of the oil into the cisterna magna.

The myelographic appearance in the normal was established on the basis of a study of 8 patients who had myelographic examinations for other reasons than a lesion of the cervical spine and who had no symptoms or signs referable to the cervical region. It was noted that the opaque medium which had passed through the lumbar and lower dorsal spine as a solid

column had a tendency to break up into droplets of various sizes as soon as it entered the cephalad third of the dorsal spine. When this happened the patient was returned to the erect position to permit the oil to collect in the lumbar sac and the examination started anew. It was further observed that when the opaque medium finally entered the cervical spine as a solid column there always was a transitory delay of the passage of the column through the lower three cervical vertebrae. Following this pause, the column usually extended to either side of the canal, outlining the axillary pouches as tiny triangular shadows with their apices directed laterally along the cervical nerves as they pass through the intervertebral foramina. By tilting the patient up and down several times it was possible to collect most of the oil in the lower cervical canal.

The changes incident to herniation of the nucleus pulposus of the lower cervical spine were found to consist chiefly of alteration of the rate of flow and modification of the roentgen appearance of the solid opaque column. In 4 patients there was a definite partial obstruction to the passage of the column in the affected region which was fairly uniform and could be repeated in the same patient with identical results. In the fifth patient there was complete block of the cerebrospinal fluid. Serial spot roentgenograms made during the period of delay showed the opaque medium first gathered in a large globule with a flat or convex base simulating a capillary configuration; then a thin trickle of medium which passed from 2 to 5 cm. into one or both sides of the spinal canal, droplets being scattered beneath this and between the lateral ribbons. In the roentgenograms with the head downward there was a characteristic inverted U or L appearance. In contrast with the normal the oil did not enter the axillary pouches. When the obstruction was complete the roentgen picture could not be distinguished from that observed in extramedullary tumors.

The 5 cases are described in short résumés. Several roentgenograms are reproduced for the purpose of illustration.

The general conclusion is reached that whereas routine roentgenographic and clinical examinations may lead to confusing results in the diagnosis of herniation of the nucleus pulposus of the lower cervical spine, myelography of the cervical canal constitutes a procedure which can provide valuable information and which, therefore, merits further careful study.

T. LEUCUTIA, M.D.

Long, L.: The Noninjection Method for Roentgenographic Visualization of the Internal Semilunar Cartilage. *Am. J. Roentg.* 1944, 52, 269.

The correct diagnosis of injuries to the knee cartilage is of special importance in military medicine where such a diagnosis eliminates a man from combat duty and usually from the service. Routine roentgenography of the knee is rarely helpful except in ruling out bone lesions and certain loose bodies.

There has been considerable literature concerning the roentgen demonstration of the semilunar cartilages by means of injections of the knee joint with gas or radiopaque solutions, but in military medicine these are considered operative procedures which may alter the line of duty on account of subsequent developments and therefore would not ordinarily be used as routine.

The author employs the noninjection method outlined by Reynolds in 1941 and in this article he publishes the results of a series of 709 examinations. The method is so simple that it is within the capabilities of a good technician.

The principle of the method is that an anteroposterior roentgenogram is made about three seconds after the end of a maneuver consisting of strong traction firm internal rotation and abduction of the fully extended leg. The thigh is held tightly against the table by a strong immobilization band with a fixed padded fulcrum against its lateral aspect just above the knee. To facilitate the easy adaptation of this fulcrum to either side of the table, the author constructed an accessory which he describes as follows. It consists of a piece of 3/4 inch plywood about 3 feet long and of width sufficient to fit inside of the metal rails at the sides of the table top. If there are no rails on the table, a flange will have to be added to each side of the board to prevent sideplay. In the center running lengthwise, is a 5 by 16 inch opening, and midway on one side of this is a padded fulcrum securely attached to the board. By simply turning the board end-for-end it may be used for either right or left knee.

The results of the examination are arranged in Table I.

The 15 cases of Group VII in which operation followed the roentgen study are arranged in another table according to the roentgen findings, operative findings and the pathological report. In 13 of these (86.7 per cent) no cartilage shadow was present in the roentgenograms. Two revealed distinct cartilage shadows with a defect conforming to the air replacement shadow.

In 13 patients one or both knees were examined two or more times with a total of 125 examinations in addition to the first one. The results of the re-

examinations are given in a third table. Surprisingly in a rather considerable number of cases in which the initial examination failed, the re-examination was successful. This is blamed partly on the lack of experience of the technician and partly on the failure of the patients to completely relax during the first examination. In any event, it is advisable to make a second or third examination whenever the cartilage does not appear to be definitely outlined at the initial examination.

The author presents some beautiful roentgenograms for the illustration of normal and various pathological semilunar cartilages. The negative shadow which appears as a result of the maneuver around the cartilage and which makes its visualization possible is the result of partial vacuum rather than of air.

The following general conclusions were arrived at by the author following this very minute and detailed study:

1. The technique of Reynolds for the localization of the internal semilunar cartilage requires careful attention to small details for success and should not be attempted after a recent injury.

2. In normal asymptomatic knees, the cartilage was visualized in 67.2 per cent of the cases in the first attempt. Re-examination increased this percent age to 75.4 per cent.

3. In pathological conditions (mostly without surgical confirmation) the cartilage could be visualized in only 10.8 per cent of the cases, which indicates that nonvisualization is a corroborative sign. When an abnormal cartilage became visible, often a defect, thinning, or absence of its wedged shape as noted. Reynolds states that the cartilage cannot be demonstrated in the presence of effusion regardless of whether or not it is injured, and this was also the author's experience. Acute tenderness was likewise found to be a contraindication to the use of the method.

4. Improvement in accuracy of interpretation may be expected when a large series of surgically treated cases can be analyzed. For the present, it is best to interpret the roentgen findings in the light of the available clinical evidence.

T. LAURITZ, M.D.

TABLE I—RESULTS OF EXAMINATIONS

	Cartilage demonstrated	Cartilage not demonstrated	Total
Group I Normal, asymptomatic knees	104 (87.0%)	15 (13.0%)	119
Group II Symptomatic knees with final diagnosis other than pathological cartilage	75 (66.4%)	38 (33.6%)	113
Group III Clinical diagnosis of pathological cartilage without surgical follow up	1* (17.0%)	5 (83.0%)	6
Group IV Probable pathological cartilage but no definite diagnosis made		41 (100%)	41
Group V Symptomatic knees with records not available for classification	18 (41.0%)	26 (59.0%)	44
Group VI Previous knee operation elsewhere but no record as to the exact procedure		1 (100%)	1
Group VII Pathological cartilage with operative confirmation	2* (3.3%)	5 (86.7%)	7

*Eight of them showed defect or thinning of the lateral portion.

**Both with defect.

Ungar E. M. Spiegler G. and Smithers, D. W.:
The Volume Localization of Deep-Seated Tumors by Means of Tomography *Brit J Radiol*
1944 17 235

In recent years more attention has been given to tumor dosages in roentgen therapy. The trend at present is not to consider the dosage at a given point within the neoplasm but to consider the tumor itself as a three-dimensional object with the rays entering into it from many fields.

The authors are concerned with reconstruction of the tumor in volume in its correct relationship to the body. It was found that tomography could be used for such a purpose. A description of the principle of tomography (sectional roentgenography) is given. An estimate was made concerning the magnification at each plane and a correction table established. In this manner with multiple films at varying levels throughout the tumor a model of the entire tumor could be reconstructed in its relationship to the body.

Tomography is a diagnostic field and it is the responsibility of the diagnostic roentgenologist to render accurate interpretation of the tomograph and to co-operate with the therapist in an effort to administer the correct estimated tumor dose. However, it is pointed out that tomography is an adjunct to routine films and does not supplant them.

MAURICE D. SACHS, M.D.

Veloso M. M. Bronchial Cancer Treated with X rays (Cancer bronchial tratado con rayos X). *Rev méd. Chile* 1944 72 616

A case of bronchial cancer in which the patient is alive and free of recurrence five years after treatment is discussed. On admission to the hospital in November 1938 the patient was forty-six years of age and weighed 60 kgm. he was in good general health and had no past history except mild attacks of bronchitis in winter. He came for examination on account of a sudden intense pain in the left half of the thorax, cough without expectoration, dyspnea, and a temperature of 38°C. Clinical examination showed a pleural friction rub at the left base and relative dullness in the same region. Roentgen examination showed slight paralysis of the left diaphragm and veiling of the left costodiaphragmatic sinus. A diagnosis of pleurisy probably tuberculous, was made and the patient sent to a tuberculosis sanitarium. Examinations for tuberculosis were negative however and he was discharged.

Ten weeks later he returned on account of pain in the precordial region and left half of the thorax, with cough, copious expectoration, sweating and chills and a temperature of 38°C. He had lost seven kgm. in weight since the last examination. There was relative dullness of the left hilar region, with a murmur indicating a cavity, medium and low rales were heard. Roentgen examination showed a cavity containing liquid. The patient was hospitalized with a diagnosis of acute lung abscess, for which he was treated with small doses of neosalvarsan

and intravenous injections of 20 per cent alcohol in glucose solution and 4 per cent emetin. His condition showed improvement but in order to confirm the decrease in the size of the abscess planigrams were taken. These planigrams in addition to showing the disappearance of the cavity, showed decreased transparency of the left upper lung field and a slight constriction of the bronchus on that side. This suggested compression of the bronchus with atelectasis due to bronchial cancer. Roentgenograms with lipiodol showed obstruction of the left bronchus and bronchoscopy showed a congested tumor which had the appearance of bronchial cancer. Histological examination of a biopsy specimen showed an anaplastic adenocarcinoma, evidently embryonic with intense karyokinetic activity and therefore, sensitive to irradiation.

Beginning July 18, 1939 a total dose of 7,500 international roentgen units was given in about three weeks the factors were as follows: individual doses from 400 to 500 roentgen units, 200 kv., 90 cm. focus-skin distance and 300 sq. cm. of irradiated surface. With a filter of 1 mm. of copper and 0.8 mm. of aluminum this gave a dose of about 2,300 international roentgens to the tumor.

The patient was dismissed without fever or pain and weighing 54.1 kgm. There was scanty expectoration. Roentgenograms have been taken at intervals since then. The roentgenograms taken before and at various periods after treatment are given. The patient is in good condition.

Hempelmann L. A., Jr., Reinhard E. H., Moore C. V., Bierbaum, O. S., and Moore, S.: Hematologic Complications of Therapy with Radioactive Phosphorus. *J Lab Clin Med* 1944 29 1030

One hundred sixteen patients with various types of hematologic dyscrasias have been treated with radioactive phosphorus at the Washington University School of Medicine, St. Louis, Missouri and 100 of these have been observed for a sufficiently long period of time to permit evaluation of the therapy. Radioactive phosphorus is a valuable therapeutic agent in the management of polycythemia vera and the chronic forms of leukemia. Its use in patients with most acute leucemias, Hodgkin's disease, reticulum-cell sarcoma and lymphosarcoma has been disappointing. The primary purpose of this communication is to call attention to the frequency with which anemia, leucopenia, and thrombocytopenia developed in the patients treated.

The appearance of toxic effects induced in the peripheral blood by radioactive phosphorus may be delayed for many weeks, presumably because with its half life of fourteen and three tenths days it continuously emits radiant energy for many weeks.

The authors used a freshly prepared solution the initial activity of which usually varied between 300

and 400 microcuries per cubic centimeter. The solution was used during a period of weeks until its strength had decayed to between 50 and 50 microcuries per cubic centimeter. Small frequent intravenous injections of radioactive phosphorus were used. The size of each dose given parenterally varied between 100 and 2,000 microcuries. Patients were usually treated two or three times a week at first. As the white-blood-cell count either approached normal in the patients with leukemia or became subnormal in the cases without initial elevation of the leucocyte count, the dosage was decreased and the time interval between treatments was lengthened. Patients with polycythemia were given larger quantities of radioactive phosphorus at much less frequent intervals. Therapy was governed principally by the changes in the peripheral blood, and an attempt was made in each case to restore the cytology of the blood to as near normal as possible and to maintain this effect.

In the cases of lymphosarcoma, Hodgkin's disease, reticulum-cell sarcoma, multiple myeloma, and giant follicular lymphoblastoma, in which the white-blood-cell count was not elevated, regulation of therapy was more difficult. Administration of radioactive phosphorus was continued in these instances until changes in the peripheral blood gave warning of a depression of bone-marrow activity. In some patients serial bone marrow aspirations were made to aid in regulating therapy. Patients with subleukemic leukemia were given amounts that were comparable with those required to regulate the subjects with elevated counts.

The most striking complication was the thrombocytopenia. The platelet count fell to below 100,000 per cubic millimeter in 44 instances and to below 50,000 in 33 of these. The fall in platelets frequently developed in patients with leukemia, for instance, several weeks or months after the leucocyte count had approached normal and most of the abnormal cells had disappeared from the circulating blood. In

some cases, thrombocytopenia occurred even after therapy had been discontinued. Of the 44 patients who developed thrombocytopenia, 38 showed clinical manifestations of abnormal bleeding.

In 56 patients there was a steady progressive decrease in the leucocyte count; in 25 the white blood-cell level first increased and then showed a progressive decrease. In 2 patients with acute leukemia there was a gradual rise in the number of leucocytes up to the time of death. Three patients who were in the terminal stages of leukemia first showed a decrease followed by a progressive increase. In the 14 others there was either no significant change in the leucocyte count or a pre-existing trend was apparently uninfluenced by therapy. Of the 41 patients who developed leucopenia apparently as the result of therapy, 6 had definite ulceration of the mouth or nasopharynx, the 35 others had no specific symptoms which could be attributed directly to the leucopenia.

Thirty-six of the 100 patients developed an anemia which seemed to be due to the therapy; this included only patients whose erythrocyte count dropped by 1,000,000 or more cells per cubic millimeter and to a level below 3,500,000.

At autopsy localized areas of necrosis in the bone marrow were observed several times. In 4 instances, the bone marrow was found to be aplastic.

There was considerable variation in the susceptibility of different subjects to the toxic effects of radioactive phosphorus. In several instances, leucopenia, thrombocytopenia, or an anemia followed comparatively small doses of the material. Much larger amounts were tolerated by other patients without difficulty. The dosage must be individualized to a high degree. The blood of patients treated in this manner should be studied at frequent intervals so that the hematologic changes can be recognized early and further administration stopped before irreversible toxic effects on the bone marrow are produced.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Romano, J. Engel G. L. Ferria, E. B. Jr. Ryder H. W., and Others. Problems of Fatigue as Illustrated by Experiences in the Decompression Chamber. *War Med. Chic.* 1944, 6: 102.

Fatigue studies on 43 adult subjects, repeatedly exposed to simulated altitudes of 35,000 feet in a decompression chamber were carried out with clinical, psychological, and laboratory tests. Physical and chemical studies have been of little value in the understanding of fatigue in persons who are not subjected to severe muscular effort, or who are not deprived of adequate sleep. The problem of fatigue in flyers does not depend totally on physical stresses.

This study considers stresses other than muscular effort which contribute to fatigue such as anxiety and individual emotional flexibility. Eight subjects were studied intensively, psychologically, and physiologically before and after the six month period of exposures. In addition to detailed personality analysis, attention was directed to the previous individual patterns of fatigue as related to different types of stress. Electroencephalographic studies were also made under varying conditions.

Three types of fatigue were observed. Muscular fatigue was most pronounced in the first or second flight and occurred in almost all subjects. It disappeared with training and was not related to decompression sickness. A second type of fatigue was related to boredom or ennui. This also tended to occur during flights without decompression sickness when the subjects remained inactive at altitude for long periods, and disappeared quickly after descent. The third type of fatigue was not related to either muscular work or boredom. It began sometimes immediately but more often a few hours after descent, and tended to diminish in frequency and intensity with experience. It was experienced by 24 of the 43 subjects. The character of this fatigue was similar to that previously experienced in anxiety stress situations and showed no direct correlation with decompression sickness in many instances. Physiological derangements could not be demonstrated quantitatively and objective evidence of such disturbances could be found in only a few instances after severe decompression sickness. Laboratory data, including the electroencephalogram, blood count, and circulatory reactions to changes in posture, revealed no direct correlation in any type of fatigue. While certain subjects experienced more pronounced fatigue after severe decompression sickness, others did not.

These data do not support the concept that subclinical bends accounts entirely for this type of fatigue. On the other hand it is likely that the diffuse tissue damage which undoubtedly occurs in

decompression sickness will as in other types of tissue damage lead to fatigue or augment and prolong the fatigue of emotional stress. The findings suggest that emotional factors play an important role in the production of the third type of fatigue. The importance of a more thorough understanding of the person who experiences fatigue is emphasized.

JOHN L. LINDBQUIST, M.D.

Ficarra, B. J., and Naclerio, E. A. The Physiochemical Disturbance in a Severe Burn. *Sur.* 1944, 16: 529.

The most neglected phase of the burn problem has been the physiochemical disturbance produced by tissue destruction. The changes reflected in the circulating blood due to severe burns in a human being have been studied rarely. Most of the data have been gathered from animal experimentation. In the treatment of burns the opportunity and facilities were available on one occasion for a detailed and continual physiochemical observation of a severely burned patient. In view of the fact that few complete chemical analyses have been made in clinical burns the following case report was considered significantly valuable.

A forty-three year-old white male was burned when his clothing became inflamed from sparks which arose from the wire he was repairing. Tannic acid was applied to the body surface by members of the fire department and he was then taken to the hospital. The patient was in shock from burns involving 60 per cent of his body surface. There were third-degree burns of both thighs, second- and third-degree burns of the right arm and forearm, and first and second-degree burns about both ankles. In addition he had a fracture of the left ankle. At this time his temperature was 99.6 F, pulse 120, respirations 26, and blood pressure, 90/50.

Nine hours after admission the patient had responded sufficiently from shock to permit treatment of the burn. One hundred cubic centimeters of whole blood were taken for study immediately after entrance. For the first sixteen hours blood-chemistry studies were done every four hours. Thereafter complete studies were made every day. On the seventh postburn day the only available vessel for obtaining a blood sample was the internal jugular vein. This was due to the fact that the burn areas prevented the use of many vessels; others became thrombosed and on that day the patient became edematous. On the ninth postentrance day the patient's temperature rose to 102 F and he became delirious. Two days prior to this a toxic erythematous rash became visible on the nonburned skin surfaces. The patient expired on the tenth hospital day in spite of the general therapy with whole blood, plasma fluids, adrenocortical extract, vitamins, chemotherapy, protein, and local treatment of the burn areas.

The anatomical findings at autopsy were as follows: primary diffuse third-degree burns of the head, chest, back and upper and lower extremities; pyoderma with ulceration; bilateral acute and chronic interstitial pyelonephritis and nephrosis; bilateral adrenal hemorrhage; passive congestion of the liver; hemorrhagic exudate; acute tracheitis; ulcerative vaginitis; mucosal hemorrhage throughout the gastrointestinal tract; cardiac hypertrophy with right ventricular dilatation; pulmonary edema and bronchobronchitis with calculi.

The significant pathological findings were revealed in the study of the kidneys, liver and adrenal gland. Among these four organs the most interesting findings were noticed in the kidneys.

Usually the kidneys were extremely large; the right one weighed 40 gm. and the left 350 gm. The capsule was thin and stripped easily. The underlying cortical surface was reddish brown in color with readily demarcated cortex and medulla. The glomeruli were grossly prominent. Microscopic examination of the kidneys demonstrated that the glomerular spaces were distended with albuminous deposit. The cytoplasm of the tubular epithelium had a ground glass appearance, especially in the proximal convoluted tubules. Many tubules contained albuminous material. A marked interstitial edema with scattered localized areas of hemorrhage was present. The renal pelvis, medulla and subcapsular region showed dense collections of lymphocytes, plasma cells and fibroblasts. The capillaries showed pronounced dilatation and engorgement.

Pathological histology of the liver showed a generalized dilatation and engorgement of the sinusoids. The liver cells indicated passive congestion. Lymphocytic nests with occasional polymorphonuclears were seen about the portal region.

The adrenal glands retained their normal histology. However, the zona reticularis of the medulla contained hemorrhagic areas. The cells had a coarse ground glass appearance. Marked interstitial edema was seen in all the zones of the medulla.

It has been generally accepted that the extensive burns are toxic, the results because of injurious elements produced by burned tissues. The quantity of liberated toxic substance which passes into the circulation is believed to be proportional to the extent of the burn. The exact nature of this toxic substance has never been determined. Formerly it was thought to be derived from the albumin of the cell and was expected to be a polypeptide. Death was attributed to the physiological pathological alterations in the internal organs due to this proteolytic substance.

From their experience with burns the authors believe that the question cannot be answered simply by stating that toxic is the cause of physiological dysfunction. If relatively minimal consideration has been given to the physicochemical changes in burns. In 1924 Davison studied intensively the sodium-chloride metabolism in burns. This was the first time that an evaluation of the blood chemistry found a prominent place in the lives of burns. He

found a significant lowering of the chlorides, it was believed to be due to a lowering of the chloride levels below the renal threshold rather than to a primary kidney change. It was further assumed that the chlorides did not fall immediately after the burn but diminished progressively during the first few days.

Fox in a recent publication, has stressed the importance of sodium in the rational treatment of the burned patient. Hypoproteinemia, contractility of body protoplasm in alterations in carbohydrate metabolism, hemoconcentration and acidosis have been noted and discussed by many observers.

The major concern in the treatment of burns is the administration of intravenous fluids that restore the blood volume and its physicochemical components to nearly normal levels. The perfect plasma is based upon the fact that extensive burns are followed by exsiccation and cellular concentration of the blood. Harkins devised a simple method of calculating plasma dosage. His formula is to give 1 cc. of plasma for every point the hematocrit is below the normal of 45.

The authors have emphasized that the intelligent management of the severely burned patient demands daily biochemical diagnosis. The facility with which an altered physicochemical state occurs merits constant checking of the blood chemistry. Therefore it can be stated that blood chemistry determination is equally as important as the diagnosis and the definitive treatment of the severely burned.

The authors found that the analysis of the metabolic and chemical data in this fatal burn case indicated sodium chloride changes by gross destruction of body protoplasm in all ratios in the electrolyte metabolism and hemoconcentration.

The acidosis which usually accompanies the burn syndrome was absent. An unexpected alkalosis occurred following the administration of citrate sodium on the fifth postburn day.

Emphasis is placed upon a study of the blood chemistry on or about the fifth day. At this time a break in the biochemical harmony occurs. This condition is manifested by an elevation of the effects of nitrogen metabolism associated with a serum protein, plasma sodium, and blood calcium.

In the treatment of this patient 10,000 cc. of fluid were administered parenterally. Of this amount 6,000 cc. were plasma and 3,100 cc. were blood.

Death on the tenth day was attributed to exhaustion and renal failure. The major factor indicating the cause of death in burns has not been established satisfactorily. It is believed that a severely burned patient dies of physical exhaustion and therefore a study of the organs involved in the process of physiology (liver, kidneys and adrenal) is essential in the determination of the problem of the ultimate lethal factor.

Herein lies the intrinsic value of blood studies of the physicochemical changes in the burned.

reflected in altered blood chemistry. The exhaustion of the aforementioned basic physiologic organs may be the cause of death when after the second week the patient seems to be improving.

This somatic distress is emphasized because during the third week the initial danger apparently has been overcome. The anxious surgeon considers the patient sufficiently improved for a skin graft. However, the disturbed chemistry has not been restored. In the presence of this metabolic discord, the administration of an anesthetic plus the surgical procedure may be sufficient to cause death.

BENJAMIN GOLDMAN M.D.

Taylor F. H. L., Levenson, D. M., and Adams, M. A. Abnormal Carbohydrate Metabolism in Human Thermal Burns. *V. England J. M.* 1944, 331-337.

In a study of 35 consecutive burned patients a high incidence of hyperglycemia, lactic acidemia and a moderate reduction in the carbon dioxide-combining power of the plasma were found. There is a high degree of correlation between these abnormalities of carbohydrate metabolism and the severity of the burn. The glucose tolerance tests made indicate that in some severely burned patients with hyperglycemia there remains a considerable ability to metabolize added glucose.

There was no evidence of liver damage in these patients as a result of the burn. In the few cases in which liver damage was found it was present before the injury being for the most part an alcoholic cirrhosis.

The abnormalities in carbohydrate metabolism presented are not inconsistent with the presence of an increased glycogenolysis together with a possible gluconeogenesis from protein. It is suggested that additional glucose be given early to burned patients.

SAMUEL KAIM M.D.

Jones, G. M.: Diabetes Insipidus; Clinical Observations in 42 Cases. *Arch. Int. M.* 1944, 74-81.

Diabetes insipidus is a syndrome produced by damage to the supraopticohypophyseal tract and is not a specific etiological entity. This fact is too little recognized by the medical profession in general. A historical summary of the experimental and clinical contributions which lead to the present knowledge and concepts of diabetes insipidus is presented, and an analysis of 42 cases is made. The causes of the diabetes insipidus in these cases are listed in Table I.

One of the striking features of the cases studied was the early age of onset of the diabetes insipidus. Any patient with symptoms of diabetes insipidus deserves the most careful study in an attempt to determine the specific pathological changes that are responsible for the symptoms. The term "idiopathic diabetes insipidus" merely indicates that the pathological cause was undetermined before death or that the polydipsia and polyuria had a possible psychic origin. The latter possibility can be eliminated by a

TABLE I—CAUSES OF DIABETES INSIPIDUS

	No. of cases	Percentage
Tumor of pituitary gland	11	26
Tumor of hypothalamus	3	5
Hand-Schüller-Christian disease	4	10
Chronic encephalitis	7	16.6
Syphilis	3	7
Post-traumatic injury to the head	3	7
Pituitary infarction (?)	1	2.4
Cerebrovascular accident	1	2.4
Subarachnoid hemorrhage	1	2.4
Hypothalamic damage, cause unknown	1	2.4
Undetermined cause	8	19
Total	43	100

prolonged urine-concentration test since the polyuria is primary and the polydipsia secondary, and the patient with true diabetes insipidus will continue to have a large volume of urine of low specific gravity with resultant dehydration and loss of weight during such a test. In any case in which such a response is obtained the diagnosis of organic damage along the supraopticohypophyseal tract should be made. Furthermore, since diabetes insipidus is not infrequently the first symptom in cases of neoplasm (occurring as early as six years before other evidence of the malignant growth in one of the cases reported here) roentgen irradiation of the hypothalamohypophyseal region may be worth while when the cause of the diabetes is undetermined. Roentgen irradiation is also of value in Hand-Schüller-Christian disease. For patients with diabetes insipidus who do not respond to therapy as specifically indicated by the etiological factor, substitution of the antidiuretic principle in the form of a solution of extract of the posterior lobe of the pituitary gland or pitressin affords notable symptomatic relief. Of the various methods of administration of this extract as replacement therapy in the absence of the antidiuretic principle the intramuscular injection of pitressin tannate in oil seems the most desirable. The intranasal application of pitressin in jelly was the least satisfactory of the methods tried in this series. The use of a low salt as an adjunct to other therapy may be of benefit in any case of diabetes insipidus. Thyroidectomy should not be performed for diabetes insipidus unless there are other specific indications for the procedure.

JOHN L. LINDBQUIST M.D.

Free, A. H. and Leonards, J. R.: Studies on the Ingestion of Large Quantities of Protein and Amino Acids. *J. Lab. Clin. M.* 1944, 29-963.

Studies are reported in 3 normal human subjects in whom comparable massive amounts of whole blood protein, muscle meat, and amino-acid mixture were ingested over an eight hour period. Studies of the blood urea, blood amino acids, urinary urea excretion, and urea clearances were carried out.

The limiting factor in determining the amount of protein or amino-acid mixture that can be ingested appears to be the rate of intestinal absorption. Large amounts of unhydrolyzed protein are more

rapidly handled by the normal gastrointestinal tract than are equivalent amounts of amino acids. It seems questionable therefore whether amino acids have any advantage in alimentation over unhydrolyzed dietary protein especially when large amounts are administered and when pancreatic proteolases are present in adequate amounts. After the ingestion of the two proteins and the amino-acid mixture the variations in the blood levels of urea nitrogen and amino-acid nitrogen were similar.

Maximum urea clearances as well as urinary urea excretion were increased after the consumption of amino acids and proteins. The extent of gastrointestinal hemorrhage can be more accurately evaluated by urine and blood-urea determinations than by blood studies alone. WALTER H. NADLER, M.D.

Wallace, D. H. and Adler Tana, P.: A Study of Vitamin C Saturation in Hospital Children. *Glasgow M J* 1944, 42: 55

Vitamin C saturation tests performed on 838 children admitted to the wards of the Royal Hospital for Sick Children during the period from October 1940 to June 1944, showed defective vitamin C nutrition in a high proportion of the children. This was most severe in the year from October 1941 to September 1942, when because of war conditions vitamin C in the diet was at its lowest.

Since febrile illnesses reduce vitamin C reserves precautions should be taken in the medical wards of children's hospitals to ensure that ample vitamin C in one form or another is given to all the patients.

The children most of whom came from the slum districts of Glasgow showed subnormal vitamin C saturation when compared with children living under good conditions. The deficiency was especially noticeable in the year when the dietary sources of the vitamin were at their lowest. It is thought that the low vitamin C saturation found in the children admitted to the hospital was partly due to the fact that many of them were suffering or recovering from various acute infections such as pneumonia or gastroenteritis.

The influence of infection in lowering the vitamin C reserves was evidenced by comparison with patients from the same social class who were admitted to the surgical wards of the hospital but who were suffering from noninfective conditions.

Frank scurvy was rare, and this suggests that optimal saturation is not necessary for average health. When repeated test doses of the vitamin were given, a high proportion of the children who were unsaturated when first tested showed suboptimal saturation within three days. Most of those who took longer to become saturated were suffering either from scurvy infection or some nutritional disorder in which there is interference with absorption from the bowel. While full saturation may not be necessary for the maintenance of health, it appears that children living in slums, where acute infections are so prevalent, should have ample supplies of vitamin C because with the onset of infection their reserves become exhausted. STEPHEN A. ZITMAN, M.D.

Powers, J. H.: The Abuse of Rest as a Therapeutic Measure in Surgery. *J Am M Ass* 1944, 113: 1079.

The author notes that rest, as a therapeutic measure is fraught with hazard. Prolonged periods of recumbency in bed are anatomically physiologically, and psychologically unsound and unscientific. Surgical wounds heal firmly even though early postoperative activity is encouraged. Infants and young children cannot be kept quietly at rest in bed after operation yet postoperative hernias are not common.

The author presents 100 consecutive patients who were allowed to sit in a chair and to walk on the first day after major operations and compares these studies with similar observations on an equal number of conservative, unselected patients who remained in bed for the traditional period of from ten to fifteen days.

The operations performed were as follows: hernioplasty for inguinal, femoral, umbilical, epigastric, and incisional hernias; appendectomy for acute appendicitis including cases of perforation with abscess and peritonitis; cholecystectomy with and without exploration and drainage of the common duct and hysterectomy and other major pelvic operations performed through an abdominal incision. The patients in both groups were all over twelve years of age.

Of the patients who underwent hernioplasty 39 were up and walking on the first day after operation and an equal number remained in bed from twelve to fourteen days. Those who were permitted early activity spent an average of nine and one-tenth days in the hospital and required five and six-tenths beds for convalescence while the other group remained in the hospital fifteen and two-tenths days and did not return to work until ten weeks after operation. No recurrences developed among those who were up on the first postoperative day while 1 inguinal and 1 femoral hernia recurred among the recumbent patients.

Of the patients with acute appendicitis, 23 from each group were observed. Those who were activated promptly returned to work in four and eight-tenths weeks, while those who remained in bed the customary time did not resume their work until eight and seven-tenths weeks after operation. There were no postoperative residual intraperitoneal abscesses that developed in the patients who were ambulatory early in the other group, 2 such abscesses developed.

Of the patients who underwent cholecystectomy 14 from each group were observed. One in the ambulatory group developed a late incisional hernia subsequent to discharge from the hospital, while 2 such hernias occurred in the patients who remained in bed sixteen and twenty days after operation, respectively. The convalescence in the hospital was materially shortened and the total average period of rehabilitation was reduced one half by early postoperative activity.

Twenty five patients of each group were observed after abdominopelvic surgery. Supravaginal hysterectomy was performed 10 times in the ambulatory group while it was performed only 8 times in the other group. Only 1 person was allowed up on the first day after repair of a cystocele, rectocele, and prolapse. The average age of the patients in the early and control series was almost exactly the same. The length of time spent in the hospital after operation and the total period of convalescence for the patients who were allowed early activity were eleven and seven-tenths days and six and seven tenths weeks, respectively for those whose regimen followed the earlier pattern; the averages were sixteen and seven-tenths days and eleven and six tenths weeks respectively.

Of 100 patients observed in each group the ambulatory patients spent ten and three-tenths days in the hospital while those who followed the traditional convalescent program averaged sixteen and one-tenth days in the hospital. This represents a saving of 580 hospital bed days. If the temperature and pulse rate are regarded as accurate indexes of convalescence such early activity is in no way deleterious. However other complications may arise.

Postoperative complications may be classified as local pulmonary, cardiac, vascular, genitourinary, gastrointestinal, and general. No local complications of major significance occurred because of early activity. No wounds disrupted. One incisional hernia developed several months after operation, an incidence of 1 per cent. Two incisional hernias, 2 recurrent hernias, 1 hematoma, and 1 silk sinus occurred among the patients who were kept recumbent for the customary postoperative periods. Serious pulmonary complications were likewise more common among the patients who remained in bed. No cardiac complications were observed among the ambulatory patients. The incidence of vascular complications was reduced but not eliminated. Postoperative inhibition of the bladder was rather common in both groups. Repeated catheterizations were much more frequent among the patients whose convalescence was spent in bed. Postoperative dilatation of the stomach and fecal impactions occurred only in the patients who remained in bed. Fever which could not be explained by reaction to operation or to the disease was observed in 5 patients among the recumbent group. In total there were 17 postoperative complications among the 100 patients who were out of bed on the first day and 46 among the same number in the unselected control group.

Accurate reapproximation of the tissues is compulsory if early activity is planned. Nonabsorbable, interrupted sutures are preferred except in the peritoneum which may be closed with a continuous stitch. Additional supporting sutures of silk worm gut or silver wire may be desirable for obese patients or in the presence of infection.

In conclusion the author notes that early postoperative walking may reasonably be of definite

therapeutic value in the prevention of pulmonary complications. Elevation of the diaphragm in the recumbent position, pooling of the tracheobronchial secretions in the finer ramifications of the bronchial tree, the patient's disinclination to cough because of pain, the limitation of maximal respiratory excursions and the invariable reduction in the vital capacity after laparotomy or hernioplasty all play some role in the etiology of postoperative atelectasis and pneumonia. The volume of the tidal air, tension of the oxygen in the alveolar spaces, oxygen saturation of the arterial blood, and the depth and rate of respiratory movements are increased by exercise.

The occurrence of 1 case of iliofemoral thrombophlebitis and 1 of suspected thrombosis in the deep veins of the leg among the ambulatory patients indicates that early postoperative walking does not entirely circumvent the formation of thrombi. It may obviate the liberation of emboli of sufficient size to precipitate a fatal postoperative catastrophe. A thrombus of this magnitude does not usually develop in an active venous circulation.

Postoperative dysfunction of the gastrointestinal tract is uncommon when early convalescent activity is permitted. Abdominal distention is rare. Enemas, rectal tubes, and poultices are seldom necessary. A regular diet can usually be accepted on the fourth or fifth postoperative day.

The absence of asthenia in ambulatory patients is impressive demineralization of the bones and atrophy of the muscles, so common after prolonged periods of rest in bed are entirely obviated.

Contrary to the opinion of the majority of surgeons, those who have advocated early postoperative walking have observed no deleterious effect as a result thereof, no increase in pain, and no greater frequency of disruption or hernia.

The improvement in morale is striking. Early discharge from the hospital effects an economy for the patient and an efficient utilization of beds by the institution. Prompt rehabilitation insures a minimal loss of time from work and the early re-establishment of normal activity.

HERBERT F. THURSTON, M.D.

Raven, R. W.: The Surgical Complications of Typhus Fever. *J. R. Army M. Corps* 1944, 83, 119.

The author witnessed several interesting complications of typhus fever among the Arabs of North Africa and ascertained that a racial resistance to this disease existed. Thus it was noted that the Russians have a high resistance, the French a moderate one and the Rumanians a low resistance with a corresponding incidence in surgical and suppurative complications.

The surgical complications of typhus fever may be classified into 3 groups: infective, vascular and ocular. Infective complications are usually manifested by abscess formation in the cephalocervical region, the extremities, the chest, the abdomen, or the perineum. Cellulitis is usually a fatal complica-

tion, and 6 such complications resulted in 100 per cent mortality. Acute parotitis was reported in 48 cases. Treatment consisted of one or more small incisions over the most prominent site of fluctuation. Pus may or may not appear but the diminution of intracapsular pressure is of value. Instead of surgery, x ray therapy over the parotid gland, especially in the nonpurulent infections may be used as a substitute.

Other reported complications include inflammation of the buccal cavity, mandible, larynx, bones and joints. Vascular complications occur in large numbers. These include phlebitis, and gangrene of the extremities of the intestine and of the skin. Gangrene of the extremities is usually of the dry type and occurs during the first weeks of convalescence. It is probably caused by a progressive obliteration of the blood capillaries and arterioles commencing in the distal part of the limb. Cutaneous gangrene may occur in the skin of the scrotum, of the extremities, and at pressure points. Ocular complications are manifested by thrombophlebitis of the orbital veins, atrophy of the optic nerve, corneal ulceration or paralysis of the third and sixth nerves. The possibility of surgical complications should be borne in mind by the attending physician and treatment instituted early. BENJAMIN G. P. SHAPIROFF, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Dowdy A. H., Sewell R. L. and Vincent J. G.
The Prophylaxis and Therapeutics of Clostridial Infections (Gas Gangrene). *Y. Fork State J. M.* 44, 44, 390.

The authors have studied over 1,500 dogs in which clostridial infections have been produced. The report is confined to the sulfonamides, penicillin, and pentavalent antitoxin as far as treatment is concerned. Of the 377 untreated control dogs 93.4 per cent died. The infectious agents were virulent cultures of the clostridia *perfringens*, *septicum*, *novyi* (strains) and *sordellii*. Mixed cultures of the inocula produced a great increase in virulence and the amount of infection had to be reduced. The presence of *staphylococcus aureus* was found not to be responsible for the increase in virulence of the inocula.

The drugs employed for prophylaxis were sulfadiazine, sulfathiazole, sulfanilamide, and penicillin. The blood levels of the different agents were determined before, during, and after administration. Sulfathiazole was the most difficult to maintain at the desired levels. A three-day treatment period was followed by seven days of observation.

With the clostridium *perfringens* there was a 15 per cent survival of the controls. With the clostridium *septicum* there were no survivals. With one strain of the clostridium *novyi* there was a 4 per cent survival and with the second strain there was none. There was a 12 per cent survival with the clostridium *sordellii*. With the 5 strains mixed there was a 6.6 per cent survival.

Sulfadiazine was the most effective prophylactic with 93 per cent survival in infections caused by the clostridia *perfringens*, 72 per cent survival in those caused by clostridium *septicum*, 80 per cent in those caused by clostridium *sordellii*, but only 4 per cent in those caused by clostridium *novyi*.

Sulfathiazole was next in effectiveness and then sulfanilamide. The clostridium *novyi* proved extremely resistant to the action of the sulfonamides. The prophylactic experiment in which 7 dogs were treated with penicillin against the clostridium *novyi* showed a 73.4 per cent survival.

Therapeutically the experiments were carried out against 7 infectious agents except in the case of the sulfonamide resistant clostridium *novyi*. Sodium sulfadiazine, penicillin, and pentavalent gas-gangrene antitoxin, or a combination of these agents were used. Auxiliary sulfadiazine was used so that it would act directly on the invading organisms when antitoxin was the definitive agent. In order to simulate battlefield conditions more closely, the wounded should have received the prophylactic treatment with sulfonamides before they reached the base hospital for the definitive treatment.

The dosage of penicillin for a treatment was from 25,000 to 50,000 units per kilo of body weight. Massive doses of antitoxin over a short period of time were deemed preferable. The results showed that with sodium sulfadiazine used individually as the therapeutic agent against the mixed infection of clostridia *perfringens septicum*, *sordellii*, and *staphylococcus aureus*, there was a 48 per cent survival as compared to a 6.6 per cent survival in the control group. Against the same infection, when penicillin was used, there was a 100 per cent survival. Penicillin was used for therapeutics only with sodium sulfadiazine as the auxiliary agent. When penicillin only was used three hours after inoculation, 25 dogs showed a 100 per cent survival. When it was used six hours after inoculation along with sulfadiazine there was an 88 per cent survival. When it was used twelve hours after inoculation along with sodium sulfadiazine there was only 8.3 per cent survival, and when it was used with sulfadiazine three hours after inoculation there was 100 per cent survival.

Penicillin was used alone twelve hours after inoculation with no survivals. The antitoxin-penicillin combination was apparently the best treatment in the advanced stages of the infection.

The survival rates are higher for the sulfadiazine-treated animals than for the sulfathiazole-treated animals. In prophylaxis sulfadiazine is the best of the three sulfonamides employed when it is given systemically in such amounts as to maintain an adequate blood level. When the contaminating organism is the clostridium *novyi*, little or no protection can be expected from any of the three sulfonamides studied. Penicillin is of little value for prophylactic treatment and could not be used routinely under battle conditions. The authors did not test the prophylactic use of the pentavalent antitoxin.

Therapeutically when gas gangrene is apparent clinically sulfadiazine should be expected to be 50 per cent effective. It is suggested that it might be best to give the initial dose intravenously in the form of sodium sulfadiazine in order to obtain therapeutic concentration of the drug in the blood. Penicillin is much superior to sulfadiazine as a therapeutic agent as it is effective against the clostridium novyi as well as the other three clostridial organisms.

Penicillin should be extremely valuable early in the disease but it becomes less valuable as toxicity progresses. Pentavalent gas-gangrene antitoxin when used in large amounts and given early is very effective. In patients in whom the condition was far advanced and toxic the last agent was the only method found to be effective and if supplemented by sulfadiazine or penicillin it became very effective. The total amount as determined should be administered within eight hours at intervals of not more than two hours.

Clinically the patient should be tested for sensitivity to the antitoxin and if sensitive, carefully desensitized. Sulfadiazine or penicillin may be used during this desensitizing period.

Experimentally no contraindications were found to the combination of all three of these drugs.

It was suggested that surgical amputation should be indicated by the state of the vascular bed and not by the infection. RICHARD J. BENNETT JR. M.D.

Quill, L. M. and Burch, J. C.: Surgical Manifestations of Coccidioidomycosis. *Ann Surg* 1944, 120: 670.

Coccidioidomycosis occurs in 2 forms localized and disseminated. The primary or localized form has been referred to as San Joaquin fever, Valley fever and desert rheumatism. It is endemic in certain areas and regions of the Southwest. The causative organism has been shown to be a fungus. There are 2 phases in its life cycle: a vegetative and a parasitic. In tissue the organisms appear as double-contoured spherules of variable size containing endospores. The appearance of these spherules is characteristic, and their presence is diagnostic of the disease. Microscopically the growth is composed of interlacing mycelia with tiny chlamydospores attached to the aerial hyphae. Infection in the primary form is the result of inhalation or rarely inoculation of the chlamydospores which have grown out on the soil. It is unlikely that the disease can become established in new areas by the migration of infected persons. Man to man contact transmission is unknown. The parasitic spherule is not very infectious and must first grow as the vegetative form. It is pointless to isolate patients with the disease but care should be taken in the disposal of sputa and dressings.

The secondary form, or coccidioidal granuloma, is much rarer. It occurs about once in every 300 or 400 primary cases. It is due to a failure of the host to localize, or keep localized, the primary infection. Development of the granulomatous form usually

Fig. 1. *Coccidioides immitis*. Photomicrogram of the organism in tissue. (Courtesy of J. B. Lippincott Co.)

occurs quickly but occasionally the interval may be years.

The primary infection is commonly accompanied by signs and symptoms of a mild respiratory infection usually bronchitis with a productive cough. There may be chills, fever, anorexia, malaise, back ache and joint pains. Within the first eighteen days, erythema nodosum appears in 1 to 15 per cent of the cases. The leucocyte count is variable. Eosinophilia occurs late fairly regularly in the disease. The sedimentation rate is elevated. The sputum contains the diagnostic spherules during the active stage. If not found the sputum may be cultured. X rays may reveal only transient changes in the lungs. Exudative lesions may be associated with cavitation. The cavities are usually single and have a tendency to persist. Cavitation is the only lesion of surgical interest occurring in the primary phase.

Once the primary infection has been localized a high degree of immunity develops. Patients react to an extract of the organism somewhat as to tuberculin. This coccidioidin test depends on a skin sensitivity to a polysaccharide substance combined with a nitrogenous radical, and is an allergic manifestation. The usual dilutions used are 1:1000 and 1:100. The test is read at twenty-four, forty-eight and seventy-two hours. It is relatively disease specific. There is also a complement fixation test and a precipitin reaction.

When the infection is overwhelming or the resistance inadequate dissemination occurs. Any tissue of the body can be involved except the gastrointestinal tract. The individual lesions are usually granulomatous cold abscesses. A variety of surgical conditions can thus be simulated. Several cases are reported to illustrate the clinical similarity of coccidioidal granuloma and certain common surgical conditions such as appendicitis, Pott's disease of the spine and pneumonia. Cases simulating cord tumor, cerebellar abscess and peritonitis have been reported.

The prognosis is grave. In coccidioidal granuloma surgical removal if possible is probably the procedure of choice. Drugs such as colloidal copper tartar emetic, iodides, sulfonamides and penicillin have been found to be ineffective. Recently immune transfusions have been used with beneficial results in some instances. The pulmonary cavities are best treated conservatively. If hemoptysis is severe pneumothorax has given good results.

SAMUEL KARM, M.D.

DUCTLESS GLANDS

Kahn, J., and Stock, R. P.: Fatal Agranulocytosis Resulting from Thiouracil. *J Am M Ass* 944: 26-358.

Leucopenia and granulocytopenia have been reported as potential dangers in the use of thiouracil when given to thyrotoxic human beings. Similar observations have been made on adult rats which were fed thiourea. A white woman, age sixty-two, was admitted to the hospital because of nausea, drowsiness and vomiting of six hours duration. She was known to have had diabetes for six years and to have been negligent both in taking insulin and in following the prescribed diet. Diffuse goiter of relatively mild toxicity had been present for about ten years. On this admission to the hospital the patient was in impending diabetic coma. The response to therapy directed against acidosis was prompt. Because of the unstable nature of her diabetes, wholly satisfactory control never was possible.

As soon as possible after diabetic acidosis had been corrected, evaluation of the patient's thyrotoxicosis was made. Exophthalmos was slight. A fine tremor of the hands was present. A labile pulse varied between 100 and 120 pulsations per minute. The basal metabolic rate on the eleventh day was plus 65 per cent on two determinations. Blood cholesterol was 164 mgm. per 100 cc.

Thiouracil was started with an initial dose of 0.8 gm. per day in 4 divided doses for two days. Thereafter the amount was dropped to 0.6 gm. per day in 3 divided doses. A favorable response to thiouracil was prompt. The basal metabolic rate had dropped in fourteen days to plus 43 per cent. The patient had gained 4 lb. and the pulse rate was 80 per minute. The response to thiouracil continued to be favorable with a gradual rise in body weight and progressive lowering of the basal metabolic rate.

On the forty-fourth day of medication with thiouracil the basal metabolic rate was plus 10 per cent and the pulse stable at 80 pulsations per minute. At this time the dosage of thiouracil was reduced to 0.4 gm. per day. Seven days later the patient suddenly complained of a swollen, dry throat and within twenty-four hours her rectal temperature rose to 95 degrees. The erythrocyte count at this time was 3,650,000 and the leucocyte count had fallen to 1,100 per cubic millimeter with 3 per cent neutrophils, 1 per cent eosinophils, and 97 per cent lymphocytes. Thiouracil was stopped immediately. A total of 30.8

gm of thiouracil had been given over a period of fifty-four days preceding the clinical development of agranulocytosis.

The patient died five days after the appearance of agranulocytosis. At autopsy the bone marrow of several ribs and bodies of the vertebrae was abundant and dark red. Microscopically the cells of the granulopoietic series appeared to be greatly reduced in number. The clinical diagnosis of both diabetes mellitus and toxic diffuse goiter was supported by the anatomic findings. Death in this case was doubtless due to the agranulocytosis with its subsequent agranulocytic angina. HAROLD C. OCHSNER, M.D.

Frame, E. G., Fleischmann, W., and Wilkins, L.: The Influence of a Number of Androgenic Steroids on the Urinary Excretion of Neutral 17-Ketosteroids. *Bull Johns Hopkins Hosp* 944: 75-95.

The authors' study confirms the results of previous investigators on the effects on 17-ketosteroid excretion of the administration of different androgenic steroid and presents the results of the administration of 4 additional steroids which have not hitherto been reported. The use of dwarfed, sexually retarded boys with very low urinary 17-ketosteroids before treatment as subjects affords certain advantages in that the possible complication of obscuring the effect of steroid administration by lowering the body's production of 17-ketosteroids is reduced to a minimum.

Eleven different steroids having an androstane or androstene nucleus were administered to sexually underdeveloped dwarfed boys ranging in age from nine to eighteen years and the effects on the neutral 17-ketosteroid excretion were determined.

The administration of the following compounds was accompanied by a significantly increased excretion of 17-ketosteroids: testosterone (free or propionate), androstosterone, dehydroisandrosterone, Δ^4 -androstenedione-(3,17), Δ^5 -androstenediol-(3 β ,17 α)-diacetate and androstenediol-(3 α ,17 α)-diacetate.

The authors conclude that for this reason the 17-alkyl androgenic steroids are valuable agents in the study of the effects of androgen administration on the endogenous production of urinary 17-ketosteroids.

JOSEPH K. NARAT, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Symmers, D.: Clinical Significance of the Deeper Anatomic Changes in Lymphoid Dissem. *Irish Ind. M* 944: 74-164.

Anatomically, chronic lymphogenous leucemia is broadly divisible into two forms, a splenomegalic form, in which lymphoid hyperplasia is preponderant or 'primary' in the spleen, and a form in which the abdominal lymph nodes or the abdominal and thoracic nodes combined are preponderantly or 'primarily' enlarged. In both forms, enlargement of the superficial nodes if it occurs at all, is secondary. The same statement applies to Hodgkin's disease,

with the addition that in this disease there is a form that is preponderant or primary in the thymus and one that is preponderant or primary in the liver. In giant follicular lymphadenopathy the preponderant or "primary" changes are most often in the lymph nodes of the abdomen. It is probable that there is a preponderant or primary splenomegalic form, but proof of this awaits confirmation by evidence adduced at necropsy. In the majority of all cases of lymphosarcoma (70 per cent) the preponderant changes are in the gastrointestinal tract in the thymus or in the abdominal or the thoracic lymph nodes rarely in the spleen. Enlargement of the superficial lymph nodes if it occurs at all is usually a later and secondary feature. The gastrointestinal so-called "pseudoleucemia" of Briquet, as its name implies, is preponderantly or "primarily" a disease of the lymphoid tissues of the gastrointestinal tract. Splenomegaly and enlargement of the superficial and deep lymph nodes, while almost constantly present, are secondary features. The distribution of the lesions in the lymph nodes of the thorax and abdomen seems to warrant the view that the causative agent of each of the lymphoid diseases enters through mucous membranes most often through the mucous membrane of the gastrointestinal tract. In other circumstances, it appears that the causative agent filters through both the mucosal follicles and the lymph nodes in the abdomen and chest, and eventually brings about hyperplastic changes in the follicles of the spleen in the thymus or its remains or in the auxiliary lymphoid foci scattered through the interstitial tissues of various organs.

Stemmerman M. G. and Auerbach, O.: The Value and Limitations of the Congo-Red Test for Amyloidosis. *Am. J. M. Sc.*, 1944 308 305.

The results of 649 Congo-red tests for amyloidosis performed on 446 patients have been reviewed in order to evaluate the test and to determine the sources of error. It has proved to be a valuable procedure, in spite of a certain proportion of erroneous results, which in the authors' series has been calculated as 24.3 per cent of false negatives and 4.2 per cent of false positives.

The presence of only minimal amounts of amyloid is the principal reason for false negative results, while technical errors are probably the chief cause of false positive reports.

The determination of the presence of Congo red in the urine within one hour after injection of the dye has been of little value in the diagnosis of amyloid nephrosis.

HAROLD C. OLSBERG, M.D.

Howe, C. W., and Warren S.: Myoblastoma. *Surg.* 1944 16 319

One of the less well recognized tumors is the myoblastoma, the type cell of which is the primitive precursor of striated muscle. Myoblastoma must be differentiated from other primitive tumors of mesenchymal type on the one hand and from rhabdomyoma and rhabdomyosarcoma on the other hand.

The two chief types of readily recognized striated muscle tumors are those occurring in voluntary and those occurring in cardiac muscle. The latter are almost all congenital and benign.

The tumor is usually first noted as a small yielding nontender mass often only 1 cm. or more in diameter. On section it is grayish pink or whitish and as a rule it is fairly clearly demarcated although it occasionally shows no definite border. Ulceration is rare and, indeed, there may be hyperplastic or neoplastic response of the overlying skin or mucous membrane.

The authors have reviewed the clinical data and microscopic findings of 104 cases collected from the literature and present 10 new cases, 5 of which showed definite malignant properties, 3 of the latter metastasized to the lungs.

Fifty-six per cent of the cases reviewed occurred in the upper respiratory and digestive tracts. Fifty-nine cases occurred in the tongue and of these 3 (5 per cent) were malignant. Eleven per cent of the total cases were malignant and of these only 3 showed proved metastasis. Age had no clear influence on the occurrence of malignant myoblastic tumors. The patients ranged from eight to eighty-one years of age although 9 of 13 were over fifty years of age.

Whenever a myoblastoma is reported to have (1) atypism of cells (2) excess mitotic figures, (3) spindle-cell or sarcomatous pattern or (4) local invasion it should be treated surgically as a malignant tumor until more is known of the nature of these growths especially if the patient is over fifty years of age. The degree of radiosensitivity and frequency of metastasis are as yet unknown. Both appear to be low.

On the basis of available data, 37 patients were treated by surgical excision, 3 by excision and electrocoagulation, 5 by excision and radium therapy and 1 by electrocoagulation.

JOSEPH K. NAKAT, M.D.

Morehead R. P.: Carcinoma in Young Persons. *Arch. Path. Chic.* 1944 38 141

Neoplasia is a growth disturbance resulting in various types of tumors which appear at characteristic times of life. In infancy and early childhood are found adenosarcoma of the kidney, retinoblastoma and malignant neurocytoma. Histogenetically these tumors are embryonic in type and are related to some stimulus from a defect in the cells of the anlage. Late childhood or the presexual period of life has a very low incidence of neoplasia, which is indicative of exhaustion of the carcinogenic factor active in infancy. During puberty the various types of bone sarcoma attain their greatest frequency. This period of life is associated with the critical stages of osteogenesis which indicates a relationship of bone sarcoma with growth initiation factors and primitive connective-tissue rests.

The author emphasizes the importance of carcinoma in the young and claims that its significance

TABLE I.—DISTRIBUTION OF TYPES OF CANCER ACCORDING TO PERIODS

Infancy and early childhood	Adenocarcinoma of (kidney) Retinoblastoma Malignant neurocytoma of gland (adrenal)
Late childhood or preadult period	Fewer tumors appear than at any other period of life
Puberty	Sarcoma of bone Tumors of adult life begin to appear and those of childhood disappear
Young Ad. lt.	Precocious cases of adult tumors increase in number
Middle Life	Malignant lymphoma Carcinoma of cervix Carcinoma of breast Carcinoma corpus uteri Carcinoma of liver Carcinoma of stomach Carcinoma of rectum
Old age	

has been lost in the maze of generalizations. Only 15 cases of carcinoma of the cervix occurring at or below the age of twenty years are reported in the literature. The author has added 3 new cases to this number. Carcinoma of the cervix in the young indicates that age influences the morphology of cancer with the adenocarcinomatous type of malignancy predominating in more than two-thirds of the cases. Carcinoma of the body and fundus of the uterus was found in 3 patients under the age of thirty. Primary carcinoma of the liver is not unusually rare and has been found in 41 infants under two years of age. This suggests that congenital factors may be related to the etiology of cancer in the liver. Other carcinogenic factors may be hereditary or environmental.

In the discussion, Bask said that in an Army hospital, 4 soldiers under the age of thirty-five were found to have carcinoma of the stomach and 5 under twenty years of age had carcinoma of the large bowel. Clinically the young are not exempt or immune to neoplastic disease.

Rector said that in Michigan there were 546 deaths from cancer in persons under the age of twenty years during a five year period.

EXPERIMENTAL SURGERY

Gibson, S., Chese, D., and Cole, W. H.: Experimental Tourniquet Shock with Particular Reference to the Toxic Factor: A Method of Production Eliminating the Influence of General Anesthesia and Nervous Impulses. *Arch. Surg.* 1944, 49.

47

Tourniquet shock can be produced consistently in animals and therefore it is particularly adaptable for study, but the extreme pain produced by the tourni-

quet makes it necessary to utilize some type of anesthesia. Prolonged anesthesia is undesirable. Moreover since nervous impulses are obviously so intensive this factor might alter the data derived from the experiment. To obviate these disadvantages the authors have adopted the procedure of cutting the spinal cord at the level of the lower dorsal or uppermost lumbar vertebra, from two to four days before the experiment is to be performed. Manipulation or operation may be conducted without pain on the lower extremities of the animal with no other anesthetic than a moderate dose of morphine. To keep the tourniquet anchored in one place a sterile nail is driven deeply into the trochanter. In the experiments in which shock is produced by the release of the tourniquet, death always occurred if the tourniquet was left in place for at least nine hours. In 10 animals studied by this method death occurred after an average period of two hours and thirty four minutes following release of the tourniquet. The average loss of plasma into the extremity before and following release of the tourniquet was only 2.1 per cent of the total body weight which is insufficient in itself to explain death.

To determine whether or not a toxin may be developed in the constricted limb and whether this may have been an important factor in the pathogenesis of shock and death, the authors performed a cross transfusion by injecting blood obtained from the distal portion of the femoral vein of the constricted limb into a normal animal. To prevent increase in shock in the animal subjected to the application of the tourniquet through loss of blood, an equal amount of blood was removed from the recipient dog and injected into the shocked animal.

Four of the 5 animals receiving blood from the constricted limb after release of the tourniquet died in from two to twelve hours after the transfusion was begun. The only dog to survive transfusion of blood which had circulated through the constricted limb was one which did not receive any blood from the constricted limb until ten minutes following the release of the tourniquet. If a toxin was present in the constricted limb it would supposedly be more concentrated in the blood draining from the limb during the first few minutes following release of the tourniquet. If this were true, survival of the animal (which however did go into shock during the transfusion but recovered afterward) might be explained.

HOWARD A. McKNIGHT, M.D.

Duncan, G. W., Irvin, J. L., and Sarnoff, S. J.: Non-protein Nitrogen and Protein Concentrations in the Serum and Cerebrospinal Fluid in Shock. *Bull. Johns Hopkins Hosp.* 1944, 75, 35.

Several investigations of problems related to shock have directed attention to possible alterations in the permeability of the membranes, particularly capillary membranes located at the site of the trauma or in more general regions. Although the barrier relationship between the blood and cerebrospinal fluid

differs considerably from that existing between the blood and interstitial fluid the cerebrospinal fluid is easily accessible and may reflect some of the general relationships and certain changes which occur in shock. The problem was approached by the authors by a comparison of the nonprotein nitrogen and protein concentrations of the serum and cerebrospinal fluid during experimental shock.

The type of shock which appeared to be most suitable for this study was that produced by experimental crushing injury, since it has been shown to be characterized by low blood pressure, progressive hemoconcentration, evidence of renal damage and death unless treatment is instituted. Fourteen dogs were used as experimental animals. Anesthesia was produced by subcutaneous injections of morphine and nembutal. The mechanical press was applied to a thigh of the animal for a period of fifteen hours at a pressure of approximately 500 pounds. At the end of this time the press was removed and the animal was observed until the arterial pressure had declined to a level between 50 and 60 mm. of mercury. In most instances an attempt was made to maintain the animal in shock for the maximum period which still would allow time for the collection of specimens of blood and cerebrospinal fluid before death occurred.

The animals of the control group were given the same amount of anesthetic and were restrained on the table for a period of time equal to the experimental periods for the animals in which shock was produced.

All of the 14 animals subjected to crushing injury demonstrated progressive evidence of shock following the removal of the press at the end of a period of fifteen hours. There was progressive swelling of the injured thigh, progressive fall in the arterial pressure, progressive hemoconcentration and evidence of renal damage. The time of collection of specimens of cerebrospinal fluid and blood, after the development of severe shock, varied from three to eight hours after removal of the press. The collection of cerebrospinal fluid specimens from animals in shock was more difficult than the collection from the control group and at autopsy the ventricles and the spinal subarachnoid space showed gross diminution of fluid in a majority of the cases.

The mean concentrations of both nonprotein nitrogen and protein in the serum and cerebrospinal fluid were found to be significantly greater in the animals in which shock was produced.

From the standpoint of the objective of the authors' investigation the distribution ratios for nonprotein nitrogen for the two groups suggest that gross alteration of the barrier relationship between the blood plasma and cerebrospinal fluid did not occur under the conditions of these experiments. The small but significant increase in the distribution ratio during shock may be explained reasonably as being due to a lag in the normal transfer and distribution of nonprotein nitrogenous substances across the barrier. The increase of the mean concentration of protein in the cerebrospinal fluid of the animals in

shock may be explained on the basis of a slight shift of water from the spinal fluid resulting from the hemoconcentration.

The mean ratios of the concentrations of nonprotein nitrogen in the serum to the corresponding values in the spinal fluid were 1.58 for the control group and 2.02 for the group of animals in shock. The mean ratios of the concentrations of protein in the serum to the corresponding concentrations in the cerebrospinal fluid were essentially the same for the two groups.

The experiments indicate that if alteration in the barrier relationship between the plasma and cerebrospinal fluid does occur in shock produced by this method it is not sufficient to permit extensive passage of the plasma proteins into the spinal fluid.

JOSEPH K. NARAT, M.D.

Bialock, A.: Utilization of Oxygen by the Brain in Traumatic Shock. *Arch. Surg.* 1944, 49: 167

Reduction in the effective volume of circulating blood in traumatic shock results in varying degrees of anoxia of the different structures of the body. The nervous system is probably more sensitive than other tissues to a deficit of oxygen and it is likely that irreversible changes take place there first. Many studies have been performed in recent years on the metabolism and blood flow in the kidneys, the liver, and other organs in shock. The brain has not received sufficient attention in this regard because of difficulties connected with methods for determining the cerebral blood flow and for collecting cerebral venous blood.

The author's studies on dogs consisted of determinations of the oxygen content of arterial blood of the oxygen content of venous blood obtained from the confluence of cerebral sinuses and of the total oxygen consumption of the animal after shock was produced by several different methods. The author appreciated at the initiation of these experiments that changes in the arteriovenous oxygen difference may not parallel alterations in the cerebral blood flow. At the same time it was hoped that information on the cerebral utilization of oxygen and the total oxygen consumption of the body would shed some light on the manner in which the brain responds to a reduction in blood volume, cardiac output and arterial blood pressure.

All of the four experimental conditions for producing shock—hemorrhage, trauma, tourniquets and burns—were associated with an increase in the arteriovenous difference of both the cerebral sinus blood and the mixed venous blood. The oxygen utilization of the cerebral sinus blood and that of the mixed venous blood, in general paralleled each other closely. The difference in oxygen content of the arterial blood and that of the sinus blood increased in the early stages of shock and this difference usually became more marked as shock developed. The early increase in the arteriovenous sinus-oxygen difference was due in some instances to an increase in the oxygen content of the arterial blood rather than to a

decrease in oxygen content of the venous blood. Alterations in the total oxygen consumption of the body throughout the course of the experiments were of great. If one could assume that the oxygen consumed by the brain also remained essentially constant, the finding of an increased utilization of oxygen would mean that the cerebral blood flow was considerably reduced. Such an assumption is not warranted.

It appears that under conditions of decreasing blood flow the brain unlike the kidneys can maintain its oxygen consumption at least partially by extracting increased proportions of oxygen from the arterial blood.

JOSEPH K. NARAY M.D.

Soto, M.: Experimental Observations on Traumatic "Shock" and a Study of the Action of Remedies in this Condition (Observaciones experimentales sobre el shock traumático y estudio de acciones medicamentosas en el mismo) *Presencia med. argent.* 1944, 3, 143.

The author reports an experimental study of shock and the effect of remedies used for it. Dogs were used as experimental animals, and shock was brought about in two ways—by opening the abdomen and exercising traction on the rectum and gall bladder and by bringing the intestines outside of the abdomen and wrapping them in compresses wet with physiological salt solution. If the animals were subjected to either of these procedures until the blood pressure fell to half its normal value they never recovered spontaneously. The author used various remedial agents after the shock had reached this stage and presents graphs showing the pulse in different stages of shock and after the remedies were administered.

He gave physiological salt solution and glucose solution in doses of 20 cc. per kilogram of weight these were repeated 4 times at intervals of an hour. This brought the blood pressure up temporarily but did not save the animals. Salt solution seemed to have a better effect than glucose solution. Hypertonic solution seemed to have a less favorable effect than isotonic solution. Sympathetic stimulants such as ephedrine, adrenalin, veratril and benzadrine had about the same effect as in normal animals except that it was less pronounced and shorter in duration. The effect was not visibly improved by giving the stimulant in salt or glucose solution. Atropine as an inhibitor of the vagus was used without any markedly beneficial effect. Caffeine, as a stimulant of the central nervous system was given up to convulsive doses without any perceptible effect. Although most authors insist that digitalis

preparations are ineffective in shock because the circulatory insufficiency is due to decrease of volume and not to heart failure, it was found that the derivatives of digitalis and strophanthus dissolved in salt solution had appreciable effects and prolonged the life of the animals. The best results were obtained with a hypotonic solution of sodium glycerophosphate to which a digitalis preparation was added. This improved the condition of animals which were in a worse condition than those helped by moraine solutions and preserved life longer, but none of the remedies saved animals that had reached a certain stage of shock. The digitalis increases the resistance of the heart to fatigue and the hypotonic solution causes a hemolysis which sets free hemoglobin, phosphatides and other substances that have a good effect.

AUGUST G. MOORE, M.D.

Ireneau, C. Jr., and Puestow C. B.: The Effect of Massive Experimental Hemorrhage on the Hepatic Function in Dogs. *Arch. Surg.* 1944, 4, 60.

Experiments were performed in order to determine whether or not massive hemorrhage could produce enough damage to the liver to give rise to hepatic insufficiency. Twelve dogs were bled from the jugular vein predetermined amounts of blood being withdrawn every five minutes for thirty minutes so that the amount of blood removed was 30 cc. per kilogram. This amount of blood loss constitutes a sublethal hemorrhage. The hepatic function tests employed were the sulfobromophthalcin sodium (bromsulphalein) test, the galactose tolerance test, the prothrombin time test and the serum phosphatase test.

The galactose tolerance test consistently showed results indicative of hepatic damage, the excretion of galactose being above normal in 8 of 11 animals. The prothrombin time was definitely prolonged in 4 of the 11 animals. The other tests gave results within the limits of normal.

The authors point out that if one or two tests of hepatic function give positive results, a certain amount of hepatic insufficiency exists, since the tests are so insensitive that a positive result must be considered significant. The wide margin of safety possessed by the liver, only from 30 to 40 per cent being necessary to maintain life is possibly the explanation for the mild impairment of hepatic function found in these experiments.

It is concluded that definite although slight impairment of hepatic function was produced by massive acute hemorrhage in these experiments.

INTERNATIONAL ABSTRACT OF SURGERY

VOLUME 80

MARCH, 1945

NUMBER 3

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

EYE

Callahan, A.: Eye Injuries at an Aircraft Plant.
J M Ass Georgia, 1944, 33 312

A series of 404 eye injuries observed between January 1942 and October 1943 is presented, with an evaluation of some of the clinical and therapeutic problems encountered in industrial ophthalmologic practice at an aircraft plant

In most instances the traumatic agents in these cases were particles of concrete or similar material or of various types of metals aluminum and light alloys in particular used in the construction of airplanes

Early recognition and treatment are imperative in all ocular injuries because the tendency of many reparative processes in the eye is toward the formation of nontransparent tissue. In this series when the injury did not respond to adequate local therapy syphilis was suspected and found responsible in a great number of cases. The average man hour loss resulting from eye injuries was appreciably decreased when pre-employment examination and serologic tests were used to rule out those individuals with physical defects and systemic diseases such as syphilis.

A technique was devised by which the patient's head was fixed firmly against the chin rest and forehead bar of the slit-lamp microscope. Analgesia was produced by 1/2 per cent pantocaine. Dissection and removal of all embedded particles with various spuds were done under direct observation with the (20X-40X) microscope.

Scant attention has been paid heretofore to a chemical sensitivity of the eye structure to aluminum compounds. However most of the cases listed under traumatic and chemical conjunctivitis were those in which small particles of this metal were adhering to the surface of the conjunctiva.

Only 3 eyes were totally lost in the entire series of cases.

Two case reports of intraocular foreign bodies are given in detail, with illustrations concerning their extraction.

LESLIE L. MCCOY M.D

Marshall J. C.: A Case of Polycythemia Vera Extraction of Both Lenses with a Satisfactory Result *Brd J Ophth*, 1944, 28 481

The case of a seventy four year-old man with cataracts and a diagnosis of polycythemia vera in which the lenses were successfully extracted, is reported in detail. A previous examination had shown the presence of retinal hemorrhages in the left eye, but in spite of this vision of 6/6 was obtained in each eye with correction after surgery

The author concludes that it is justifiable to carry out surgery in cases of polycythemia vera if it is required. Even in severe cases the retinal lesions may return to normal or leave minimal damage. Fundus examination in some cases may cause confusion with cerebral tumors because of the edema of the optic discs

WILLIAM A. MANN M.D

Asbury M. K. Epithelial Tumors of the Iris.
Am. J Ophth, 1944, 27 1094

Four epithelial tumors of the iris are described in detail, including a previously reported in the literature. The author describes these as a group of relatively benign epithelial tumors which affected principally the iris and arose presumably from the posterior iris epithelium or the anterior edge of the ciliary epithelium. They were circumscribed but not encapsulated with a wide variation in pigmentation. In spite of the benign histological characteristics there was a definite tendency toward local invasion and destruction. They might be classified as medulloepitheliomas or perhaps as a group between truly benign epithelial hyperplasia and malignant epithelioma.

WILLIAM A. MANN M.D

EAR

Matthews, R. M. S. Obstruction of the Eustachian Tube and Barotrauma in Air Crews. *Brd M J*, 1944, 2 523.

Obstruction of the eustachian tube and otitic barotrauma present one of the greatest problems of the medical officer on a flying station. The term

eustachian obstruction" is used to represent all degrees of impaired patency up to complete block while otitic barotrauma refers to those cases presenting persistent abnormal drum appearances and hearing changes. The anatomic arrangement of the tubes is such that on ascent the relative increase of pressure in the middle ear is relieved spontaneously at definite intervals. On descent however spontaneous equalization of pressure does not occur and voluntary effort is necessary to allow air to enter the collapsible pharyngeal opening. This is done by swallowing and sometimes by manipulating the mandible by wide chewing movements or by auto-inflation. Eustachian obstruction causes a sensation of blocking of the ears, and the drum may be slightly invaginated in appearance. If the man has discovered his condition through flying there may be barotraumatic changes as well. On attempting auto-inflation no movement is observed and no subsequent click is heard. The determination of whether the tubes are patent may be a problem since normally movement of the drum is not always visible on auto-inflation nor is there always an audible click. The presence of a cold does not always cause tubal obstruction and mild forms of chronic rhinitis, pharyngitis and tracheitis do not necessarily curtail flying duties. Otitic barotrauma is indicated at first by a sensation of fullness then increasing deafness and lastly pain. In slight cases the drums appear invaginated and injected with slight impairment of hearing. In moderate cases hemorrhagic areas appear in the drum and in these recovery takes longer. In severe cases an effusion may occur into the middle ear and in rare cases there may be rupture of the drum.

Prevention is of greatest importance. The time spent by the medical officer in instruction of the flying personnel is well repaid.

The treatment used for eustachian obstruction consists in the instillation of 3 drops of $\frac{1}{4}$ per cent ephedrine in liquid paraffin in each side of the nose while the patient is in the horizontal position with the head dorsiflexed on the neck until the tip of the chin and the ear are in the same vertical plane. After three minutes auto-inflation is attempted. There have been no cases of spread of infection to the middle ear. Inhalations of menthol and eucalyptol in hot water are used afterward. If relief is obtained the man is limited to nonoperational duty for one night. If the tubes are still not patent after treatment the patient is confined to ground duties. The average time for recovery to fitness for full flying is two and five-tenths days. Benzadrine and karsodrine inhalers are convenient for air crews and are used before and after descent. Otitic barotrauma is most satisfactorily relieved by immediate ascent to a height above that at which barotrauma began and subsequent slow descent with frequent auto-inflation. On landing, treatment is necessary at the earliest opportunity the first essential being to obtain patency of the tubes. If the use of a vasoconstrictor and Valsalva's method is unsuccessful, politizeriza-

tion is used. Catheterization is seldom needed. The effects of the trauma must be resolved before flying is resumed. In the cases referred to this required an average of twenty and four tenths days.

JOHN R. LINDSAY, M.D.

Ullmann, E. V.: Traumatic Deafness in Combat Flyers. *Arch. Otolaryng. Chlc.*, 1944, 40: 174.

A total number of 900 officers and 1,355 enlisted flying personnel were examined after combat duty. Of this series 100 officers and 40 enlisted men are given special examination of the acoustic mechanism. These men were between the ages of twenty and thirty years. There was no complaint about their ears on questioning except an occasional humming and ringing in one or both ears. There was no trauma to the drums. Of this series only 3 officers showed no damage to the acoustic mechanism, while 97 showed definite changes. Three per cent showed a loss of 100 decibels in one or more frequencies; 71 per cent showed a loss of 50 decibels in one or more frequencies; and 12 per cent a loss of from 10 to 25 decibels in one or more frequencies. In 6 cases the damage was traced to the middle ear.

Sixty six per cent of the officers showed a fatigue notch at frequency 2,806. 16 per cent at 4,000, and the remaining 18 per cent had mixed forms of hearing loss in which the original fatigue notch could no longer be distinguished. The time which had elapsed between the last flight and the audiogram was from ten to six weeks.

JOHN F. DUNN, M.D.

Swanson, C. A., and Baker, D. C., Jr.: The Use of Penicillin in Diseases of the Ear. *J. Am. A. O. A.*, 1944, 36: 616.

The Penicillin Committee at the National Naval Medical Center believes that the intramuscular administration of the drug is the most practicable. In order to insure the therapeutic effectiveness of the drug, this Committee stresses the importance of two conditions:

1. The maintenance of adequate nutrition and a positive nitrogen balance in patients who are receiving the drug.

2. Accurate preliminary bacteriologic studies to determine that the pathogen is an organism susceptible to the drug.

Infectious diseases of the ear can be effectively treated with penicillin because the anatomic structure of the ear permits the local administration of the drug and because the organisms causing most acute infections of the ear are usually in the group believed to be susceptible to the drug. Fowler made a study of 452 consecutive cases of acute otitis media. If his statistical analysis of the causative organisms in that series is correct, then 90 per cent of the organisms are susceptible to penicillin.

In this study the sodium salt was used. It was given by continuous intravenous injection, intramuscular injection or local instillation. In 1 instance a combination of the intramuscular and local routes was used.

The author summarizes his article as follows:

In acute otitis media penicillin is administered by intramuscular injection. The amount of drug necessary depends on the causative organism and the severity. Staphylococcal infections usually require a greater amount than those due to streptococci. The drug should be continued after the patient seems well to avoid possible relapse.

When surgical intervention is done in acute mastoiditis it can be supplemented by penicillin administered either intramuscularly or by local instillation into the mastoid cavity. In 1 case, penicillin seemed to shorten convalescence and hasten recovery from facial paralysis.

In acute labyrinthitis penicillin can be administered by the continuous intravenous injection method.

Special cases of chronic otitis media can be treated successfully by the local instillation of penicillin into the middle ear. The patients best suited to this therapy are patients with chronic discharging ears caused by organisms susceptible to penicillin and with large perforations of the drum with no evidence of granulations or cholesteatomas. The pneumatic otoscope is good to force the drug into the middle ear and the penicillin can be sealed in by means of cotton impregnated with a bland ointment.

LUCIAN L. MCCOY, M.D.

Kellemen, G.: Fractures of the Temporal Bone. *Arch. Otolaryng., Chic.* 1944, 40: 333

The author presents a collection of 80 photomicrographs covering a series of 18 deaths due to skull fracture involving the temporal bone. These deaths occurred from trauma induced by moving vehicles and falls from high places.

For comparison, photomicrographs taken in cases of craniotomy for delivery are included. The pictures dealing exclusively with human material demonstrate the variations of temporal fractures with their effects on the different component tissues of the external middle, and internal ear.

After the usual fixation, decalcification and embedding, the sections were cut chiefly in the horizontal plane, with the exception of a small group which were cut vertically. All were stained with hematoxylin-eosin.

NOSE AND SINUSES

Butler, D. B., Greenwood, G. J., and Ivy, A. C.: Reduced Atmospheric Pressure as a Form of Treatment for Paramaxillary Sinusitis. *Arch. Otolaryng., Chic.*, 1944, 40: 366.

The authors state that of 125 patients who were treated for chronic sinus disease in a high-altitude chamber by rapid decompression of the atmospheric pressure to 523.6 mm. of mercury 89.5 per cent experienced subjective improvement at the conclusion of their course of treatment.

Of 29 patients who were followed up by serial roentgen studies after the instillation of radio-

opaque oils 17 (58.6 per cent) showed improvement in the roentgenogram after the decompression treatments.

Of 42 patients who were studied by repeated rhinologic examination, 30 (71.4 per cent) showed improvement in their sinus condition after being treated by decompression.

A total of 2,259 treatments were given. The average number per patient was 18.1.

Decompression therapy is a simple nontraumatic form of treatment for subacute and chronic sinus disease.

JAMES C. BRASWELL, M.D.

Putney, F. J.: Uses of Penicillin in Diseases of the Nose and Throat. *J. Am. M. Ass.* 1944, 126: 620.

The author presents 9 cases of sinus diseases in which penicillin was administered because life was endangered. It was found that acute conditions responded better than chronic ones. In chronic cases the infection often became active after treatment was terminated. Failure to respond to penicillin is attributed to resistance of the organism to the drug. The author believes that if the condition shows no improvement and the purulent drainage continues after three or four days of penicillin therapy sensitivity tests should be performed. Osteomyelitis still requires surgical intervention which is best performed during the period in which the infection has been checked by penicillin. This drug is effective against sulfonamide resistant organisms and cases which had had sulfonamide therapy were as much improved by penicillin as those which had not been treated with sulfonamides. There were no toxic reactions systemically or locally. Penicillin was used in 6 cases of osteomyelitis (of the frontal bone in 5 cases and of the frontal and maxillary bones in 1 case) and in 3 cases of orbital cellulitis secondary to sinusitis. In chronic osteomyelitis penicillin therapy for several months may prevent the need for extensive surgery. Brain abscess or intracranial abscess and orbital cellulitis occurred in 3 cases of osteomyelitis without any relation to the response to the drug.

In addition to the local use of penicillin 24,000 units were given intramuscularly every three hours followed by 15,000 units every three hours when the condition improved.

Prompt healing occurred, but the underlying sinusitis was unaffected in 3 cases of orbital cellulitis; sinus surgery was necessary in 2 cases. These patients had been given sulfonamide therapy previously without improvement.

In 1 case of cavernous-sinus thrombosis death occurred on the eleventh day of therapy. 400,000 units of penicillin had been given in the first two days by continuous intravenous drip and this was followed by 25,000 units given intramuscularly every three hours thereafter.

Acute infections of the maxillary sinuses have been cured after several irrigations with a solution of 250 units of penicillin per cubic centimeter. In Vincent's infection of the mouth and of the tonsils the

organisms disappear after a few days of systemic penicillin therapy.

In discussing this article VORSTER recommended a solution of 500 units per cubic centimeter for gonorrheal ophthalmia. 4 drops of this solution to be instilled every hour. Smears and cultures from the conjunctiva became negative after twenty-four hours and there were no recurrences. The penicillin should be continued until at least three consecutive daily examinations are negative.

Penicillin has also been used for irrigation of the lacrimal passages in cases of chronic suppurative dacryocystitis. A cc of the 500-unit solution are given daily. After the second irrigation the secretion usually becomes negligible and after several days it becomes clear.

KOENIG obtained good results in early acute dacryocystitis with 15,000 units of penicillin every three hours around the clock for seven days until the drum resolved and the landmarks returned. Then 10,000 units for three or four days and 5,000 units for three or four days more. HANSEN used heparin in conjunction with penicillin in carcinoma of the thrombosis. PEPPER emphasized the importance of surgery in lateral sinus thrombosis in conjunction with penicillin therapy. JOSEPH ZIEGLER, M.D.

ILGEN, F. Z. and Thornell, W. C.: Malignant Tumors of the Nasal Cavity. Report of 3 Cases in Which a Frontothmoid Approach was Employed. *Arch Otolaryngol* 1944 40 395.

Many methods of approach to the nasal cavity and paranasal sinuses have been devised for removal of benign and malignant tumors and for treatment of suppurative disease of the paranasal sinuses. The authors review various procedures that have been used since 1891 and describe a method of approach they have used with satisfaction in certain selected cases in which malignant disease was present but in which there was little or no roentgenological evidence of involvement of bone. They report 8 cases.

Carcinoma within the nasal cavity is most likely to be found on the septum or high on the lateral wall of the nasal passage. Recent nasal obstruction and increased nasal discharge or purulent discharge with bleeding should suggest the possibility of malignant disease. Although nasal obstruction is often attributed to polyps, recent nasal obstruction particularly when the patient is more than forty years of age is not likely to be due to polyps. Far too frequently such so-called "polyps" have been removed repeatedly without a suspicion of carcinoma and without pathological examination of the removed tissue. Such mismanagement allows carcinoma to advance until removal is impossible. If a mass in the nose bleeds readily on slight trauma or if its removal is followed by free bleeding, a malignant lesion should be suspected until some cause other than carcinoma has been found.

A carcinomatous mass which may not be primary in the nose may be found in a nasal passage. It may be an extension from the maxillary sinus or from the

ethmoid cells. Such a mass in the nose, whether or not it is primary, often is ulcerated and infected. This probably is due to trauma from crusting and perhaps is aggravated by the patient's efforts to clear the nostril. If a specimen is obtained for biopsy the instrument may remove only laminated necrotic portions of the tumor. Correct diagnosis on examination of such tissue is difficult or impossible. A negative report, therefore, must not be accepted with complete assurance until it is certain that a representative specimen has been examined by the pathologist.

Roentgenograms of the paranasal sinuses are essential in cases of tumor. In a number of the author's cases the sinuses appeared cloudy on the side on which the lesion was situated and clear or comparatively clear on the opposite side. This finding suggests obstruction due to neoplasm rather than an inflammatory process. Erosion of bone indicates extension of the malignancy beyond the nasal mucosa. The final diagnosis rests on biopsy. Determination of the degree of malignancy by grading according to the method of Broders is of great aid in deciding on the best plan of treatment.

Treatment of malignant disease within the nasal cavity when the roentgenogram reveals little or no evidence of involvement of bone requires adequate exposure (1) to ascertain the extent of the tumor and to find its point of attachment, (2) to permit proper control of hemorrhage and (3) to permit removal of the tumor and if necessary accurate implantation of radium. In some of the author's cases, the tumor, although large, was attached by a narrow pedicle. Without adequate exposure it would have been impossible either to ascertain this or to carry out accurate removal.

The incision is started just under the unshaven eyebrow, 1 cm. lateral to its inner extremity. It extends medially and then downward midway between the inner canthus of the eye and the middle of the dorsum of the nose, then down the nasofacial sulcus to end just below the free edge of the nasal bones. The incision is carried through the soft tissues and periosteum and down to the bone. Continuous suction throughout the operation is employed and bleeding points are ligated or coagulated with the electro-surgical unit. By means of a sharp periosteum elevator the periosteum is elevated from the bone medially as far as the middle of the nose and laterally as far as the lacrimal bone care being exercised to avoid damage to the lacrimal sac. Elevation of the lacrimal sac from its fossa and of the periosteum from the lamina papyracea may be required if extension of the tumor into the ethmoid cells makes it necessary to explore the whole ethmoid region. An incision is made through the nasal mucous membrane along the lower free edge of the nasal bone and the mucous membrane is freed from its undersurface of this bone. Access to the nasal cavity is then gained by using a rongeur to remove portions of the nasal bone and of the nasal process of the maxillary and frontal bones, after which

an incision is made through the nasal mucous membrane parallel to the skin incision to expose the interior of the nasal cavity. The point of attachment and extent of the tumor then are determined. If the attachment is mainly in the ethmoid region it becomes necessary to expose the ethmoid cells by removal of the lacrimal bone and a portion of the lamina papyracea of the ethmoid bone. If the attachment is in the region of the maxillary ostium it usually is advisable to open the maxillary sinus as is done in the Caldwell-Luc operation and to examine this sinus carefully for extension of the tumor. Examination of the frontal or sphenoid sinuses may be necessary. After removal of the tumor the point of attachment is thoroughly electrocoagulated and radium is applied over the coagulated region. The radium is held in place with gauze packing so arranged that both the radium and packing can be removed through the nostril. The wound is then closed with subcutaneous interrupted catgut sutures and the skin edges are approximated with black silk. A pressure dressing is then applied. The sutures are removed in three or four days. The scar usually is quite inconspicuous.

MOUTH

Fig. F. A. and Rowland W. D. Primary Tumors of Stensen's and Wharton's Ducts. *Arch Otolaryngol.*, 1944, 40: 175

A tumor arising in Stensen's or in Wharton's duct is rare, but 2 cases of adenocarcinoma of the main salivary ducts have come under the observation of Figg and Rowland in recent years and in addition 2 inflammatory nodules occurring without salivary calculi have been encountered in these structures.

The symptoms complained of in the cases of true neoplasm were not uniform. In one case they were those characteristic of recurring obstruction of Stensen's duct, and in the other (the case of adenocarcinoma of Wharton's duct) the patient had noted two small, tender nodules in the right side of the floor of the mouth situated anteriorly along the course of the submaxillary salivary duct. These had increased steadily in size but had not produced evidence of obstruction to the flow of saliva.

The tumors were firm movable, slow growing nodules and each appeared to be encapsulated within the wall of the duct, so that they were relatively easy to remove. They were excised the duct being amputated and in one of the cases the proximal stump of the duct was inserted into a stab wound in the cheek posterior to the site of the original orifice. Interstitial radium therapy was given to the operative wounds.

The two distinct nodules present in the submaxillary salivary duct in the second case proved to be malignant.

Burger, R. E., and Lehman, E. P.: Leontiasis Ossea Complicated by Marjolin's Ulcer. *Surgery* 1944, 16: 542

The author states that this case of leontiasis ossea, originating in youth, seems to belong to Group I of Monti's classification. Although it adds nothing to our knowledge of the etiology of the disease, it presents several aspects of interest.

In the first place the spontaneous sloughing of the dense maxillary lesions with apparent local cure is unusual. This was presumably the result of infection similar to the process in the mandible for which the patient was first treated at this hospital. The

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 1. Photograph of the patient in 1930, revealing the large lower jaw.
Figs. 2 and 3. Photographs taken November 1943 show

ing the regression in the visible epidermoid carcinoma and thenarked increase of puckering of the flap, possibly due to infiltrating tumor

arrest of the disease in this area may have protected him from the effects of craniostenosis. It raises the question as to whether radical excision of the diseased areas in an early stage might modify the gradual spread of the lesion. Coppo is stated to have reported a case of resection of the right superior maxilla for leontiasis ossea.

The present case is also interesting on account of the enormous size of the jaw lesion which in itself caused complete disability. One of the earlier cases shows a tumor of the jaw comparable to the present example. In the third place, the case illustrates the spread of the process into the upper cervical vertebrae a phenomenon reported previously. The limitation of the process to that portion of a bone arising in a simple anlage as described by Mayer is illustrated by the escape of the intermaxillary process although the superior maxilla on each side was involved to a marked degree.

Finally the complicating epidermoid carcinoma which determined the outcome of the case is unique. This neoplasm is unquestionably of the same nature as Marjolin's ulcer occurring in chronic ulcer of the skin and in chronic sinuses. The incidence of epidermoid carcinoma in a buccal fistula has not been made the object of a search of the literature but it must be very rare. JAMES C. BRASWELL, M.D.

PHARYNX

Szanto, P. B. and Hollender, A. R.: Tuberculosis of the Nasopharynx. *Ann. Otol. Rhinol.*, 1944, 53, 303.

Tuberculosis of the nasopharynx has been a neglected medical problem. As a complication of pulmonary tuberculosis its incidence is greater than that of tuberculosis of the larynx.

Among 134 consecutive autopsies in which a general pathological study of the nasopharynx was performed there were 24 subjects with various forms of pulmonary tuberculosis, and, of these, 18 (75 per cent) showed tuberculous involvement of the nasopharynx.

Histopathological study is often essential for a positive diagnosis of nasopharyngeal tuberculosis.

The nasopharynx may be the site of a persistent focus of tuberculous infection, and this may frequently explain the source of reinfection of the lungs in persons who have previously experienced an arrest of pulmonary involvement.

It is suggested that a plea is made for careful, routine clinical investigation of the nasopharynx in all rhinolaryngological examinations, especially in patients with pulmonary tuberculous disease. JOHN F. DILLER, M.D.

Shirer, J. W.: Modification of the King Operation for Bilateral Paralysis of the Vocal Cord. *Ann. Surg.* 1944, 20, 617.

Shirer states that his modification of the King operation is simple and provides a sufficient and

adequate airway for removal of the permanent tracheotomy tube. JAMES C. BRASWELL, M.D.

Clerf, L. H.: The Pre-epiglottic Space: Its Relation to Carcinoma of the Epiglottis. *J. A. Otolaryng. Chlc.*, 1944, 40: 177.

The pre-epiglottic space is described by anatomists as triangular or funnel-shaped in sagittal section, with the base directed upward. It is an actual space, filled with cellular and adipose tissue; it contains no lymph nodes but is traversed by lymphatic vessels. The anterior and anterolateral walls are formed by the upper portions of the wings of the thyroid cartilage and thyrohyoid membrane. This membrane is strengthened by elastic fibers in the midline and at all the tips of the greater cornua of the hyoid bone forming the median and lateral thyrohyoid ligaments. It is pierced on each side of the midline by the superior laryngeal vessels and the internal division of the superior laryngeal nerve, and it also transmits a few efferent lymphatic vessels. The base is closed by the hyoepiglottic aponeurosis or ligament which extends from the upper margin of the body of the hyoid bone to the anterior surface of approximately the middle of the epiglottis and corresponds to the bottom of the vallecula. The posterior boundary is formed by the epiglottis extending from the hyoepiglottic aponeurosis above to the thyroepiglottic ligament, which is situated immediately above the anterior commissure. Since the lower part of the epiglottis becomes narrowed, the remainder of the posterior boundary of the pre-epiglottic space is formed by an elastic membrane. This can, therefore, be considered as the weak wall of the pre-epiglottic space, as the epiglottis itself affords little protection against cancerous invasion consisting as it does of thin yellow elastic cartilage.

Fig. 1. A, Sagittal section of the larynx showing the pre-epiglottic space and its boundaries. The thyroid membrane and the thyroid cartilage are anterior. The hyoepiglottic aponeurosis above forms the base and the epiglottis and the thyroepiglottic ligament are posterior. B, Schematic drawing to show the defect or weak portion of the pre-epiglottic space, which is formed by the epiglottis from the level of the hyoepiglottic aponeurosis above to the thyroepiglottic ligament below. The lateral margins are closed by elastic membrane.

Fig. 2. A, Extensive cancer of the vestibule which extended a considerable distance along the left ventricular band, crossed the anterior commissure and involved the anterior end of the right ventricular band. The lower two-thirds of the posterior surface of the epiglottis also was involved. Invasion of the pre-epiglottic space was widespread but had not penetrated deeply. B, Cancer of the vestibule of the larynx which involved the extreme anterior ends of both ventricular bands. There were no disturbances of the voice. Although the epiglottic involvement was extensive, it could not be visualized by mirror laryngoscopy because of an overhanging epiglottis. Invasion of the pre-epiglottic space extended to the median thyrohyoid ligament. C, Extensive invasion of the pre-epiglottic space by a vestibular cancer which exhibited a relatively small surface lesion. Because of the close proximity of the invading mass to the hyoepiglottic aponeurosis, incision across the pre-epiglottic space would have resulted in incomplete removal of the cancer.

which exhibits many depressions even perforation and rarely undergoes ossification.

The anterior invasion of the pre-epiglottic space is important for it cannot be determined by mirror laryngoscopy or by direct examination. While much information can be secured with lateral roentgenograms of the larynx, these commonly exhibit only the more dense portions of the cancer. It is common to find cancer cells by microscopic examinations of the pre-epiglottic space well beyond the apparent anatomic margins of the growth. The thyrohyoid membrane and the hyoepiglottic aponeurosis offer marked resistance to neoplastic invasion so that in cases of pre-epiglottic invasion, involvement of the base of the tongue or penetration of the thyrohyoid membrane to the front of the neck is rare. There commonly is metastasis to the regional lymph nodes long before this occurs.

The lymphatic drainage from the base of the epiglottis and the anterior extremities of the ventricular bands is carried across the pre-epiglottic space through the thyrohyoid membrane to the upper nodes of the deep cervical group. Occasionally one or more vessels pass upward and terminate in a node situated below the posterior belly of the digastric muscle, but metastasis to this is uncommon. In 2

recent cases of carcinoma of the base of the epiglottis, Clerf discovered small nodes immediately above the hyoid bone on the mylohyoid muscle. These apparently were submental nodes which, usually arranged in transverse direction, occasionally may be placed vertically and then one is in close relation to the hyoid bone. In these 2 cases the position of the submental nodes apparently conformed to the latter arrangement. In neither of these was there any histological evidence of carcinoma. Since carcinoma of the anterior portion of the larynx above the vocal cords invariably perforates the epiglottis and commonly invades the pre-epiglottic space before it is recognized clinically it is necessary to deal surgically with this space. Invasion through the hyoepiglottic aponeurosis is rarely observed therefore a surgical approach which does not enter the pre-epiglottic space should be employed. If one removes the hyoid bone with the larynx by incision through the muscles above it and keeps the operation above the hyoepiglottic aponeurosis the incision always is through normal tissue. Laryngectomy with extirpation of the pre-epiglottic space, or pre-epiglottic laryngectomy would seem to be the rational surgical procedure to practice in all these cases.

J. M. MOXA, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Harvey A. M., and Kuffler S. W.: Motor Nerve Function with Lesions of the Peripheral Nerves: A Quantitative Study. *Arch. New Psychiat. Chic.*, 1944, 52: 317

A simple test has been devised to determine the localization and extent of nerve injuries as well as to estimate quantitatively the recovery of function or the effect of treatment. This test consists of recording by means of electrodes—similar to the recording of encephalographic findings. The electrodes are carefully applied over the muscles to be tested and the leads are recorded through a connection with an electrocardiograph or an electroencephalograph. Nerve stimulation is produced at a higher level by breaking the current flow in the primary of an induction coil with a Morse key (or any suitable type of contact breaker). Two stimulating electrodes lead from the secondary coil to the patient, one "indifferent" which consists of a large copperizing plate in contact with the patient's extremity 10 or 20 cm. above the point along the nerve to be stimulated. The second stimulating electrode consists of a small round metal disc attached to the end of a hardwood rod covered by gauze and lint. The arm must be held as quietly as possible during the recording. Stimulation of the nerve for consideration is accomplished at a suitable point where it is most accessible. The maximal motor nerve stimulus is applied by the stimulating electrode and the action potential is then recorded from the recording electrode leads to the recording device. A group of normal action potentials for various muscles resulting from maximum motor nerve stimulus, has been recorded. A comparison with these figures, more particularly with those of the opposite sides of the body, allows one to estimate the degree of nerve function present.

This test has been advocated for differentiation between organic and hysterical paralysis, as well as for estimates of recovery following peripheral-nerve disease or injury. **HOWARD A. BROWN, M.D.**

Harvey A. M.: A Type of Neuritis Associated with Malarial Fever. *Bull. J. Neurol. Hosp.* 1944, 75: 225.

A study of a group of malarial patients with various neurological manifestations or involvements of the nervous system is presented in this report by the author. The symptoms were very protean in character and in the milder cases were largely subjective in nature.

The subjective sensory manifestations consisted of "numbness" drawing sensations in the muscles and the feeling of an extremity going to sleep. These were often bilateral and of very short duration, appearing after exercise or at night

awakening the patient from sleep. More severe subsequent attacks were associated with detectable neurological signs, such as hyperalgesia, hypalgesia, or hypesthesia. The areas involved were varied—peripheral radicular or glove type in distribution.

Signs of motor disturbances were noted during the subjective complaints of "drawing" sensations and comprised either involuntary fascicular movements or gross contractions of the flexors of the forearms and fingers as well as occasional involvement of the lower extremities. These manifestations, which persisted for several days to weeks were all accompanied by hyperalgesia.

Sympathetic autonomic irritation was manifested by cold blotchy cyanotic, hyperhidrotic areas in the site of the neural involvement. This occurred only in the more severely affected cases.

It is of interest that although the majority of these cases occurred during the first or second attack (including the period immediately following the attack) organic signs of neural involvement were more pronounced during subsequent attacks. The data given do not correlate the amount or period of medication; however it is understood that all of the patients were under medication at the time that they developed their neurological signs.

The author endorses Anderson's pathological findings that a vascular basis is the cause of the damage to the nervous system since the symptoms are best accounted for by this explanation.

JACK WOOD, M.D.

BRAIN AND ITS COVERINGS CRANIAL NERVES

Roos, W. D., and McNaughton, F. L.: Head Injury: A Study of Patients with Chronic Post-traumatic Complaints. *Arch. New Psychiat. Chic.* 1944, 52: 255

The cause of post-traumatic complaints or syndromes has passed through many phases of terminology and theorization. The authors present an evaluation derived from a careful study of 93 head injury subjects by physiological, psychological, and neurosurgical means.

The severity of the injury was rated according to post-traumatic amnesia, the number of red cross of the spinal fluid x-ray evidence of damage to the skull and abnormal findings on neurological examination. Both the electroencephalographic and pneumoencephalographic studies rated by Jaxer and Child respectively were found to show a fair correlation with the degree of injury. After a period of approximately two years the electroencephalographic abnormalities regressed while the pneumoencephalographic abnormalities persisted.

The personality of each patient was carefully evaluated by planned psychiatric interviews. Six

nal factors were tabulated according to type and their relation with the injury. Various psychological tests were used. The Shipley-Hartford test showed relation to the severity of injury. The Kraepelin continuous subtraction test and repetition of digits were of no definite help in this study. Striking results, however, were obtained by the Rorschach test differentiating the psychogenic from the cerebral organic disturbances. Repeated testing revealed a continuous flux which varied with the improvement of the condition. By means of the Rorschach method and psychological or personality factors the patients were classified and rated according to the degree of disability or instability revealed in each case.

Headaches have been one of the most common complaints of the patients after head injury; these are divided into several types. The localized and migrainous variety were more frequently associated with organic disturbances while the generalized and tense headaches were associated with psychological factors. Patients with localized headaches were found to be in better condition than those in other groups. The Rorschach test revealed a low instability and high disability rating which corresponded with the evidence of organic disturbances in electroencephalographic and pneumoencephalographic tests. It was of interest to note that even this group of patients were influenced by personal situational factors.

A re-evaluation of the subdural and spinal insufflation treatments was suggested by Penfield, who first used these procedures. It was found, however, that the long term results were no better than the results following pneumoencephalograms, and that for some of these patients could the influence of other factors be ruled out. The results in a few patients treated by a direct operative procedure suggest a limited application of such measures in carefully selected cases. The use of prostigmine was also of value. Its effect upon postural vascular responses is shown by slowing of the pulse rate, but there was no alteration of the headache.

The main concept carried throughout this study is that there is no specific syndrome following head injuries and that in all both organic and psychogenic factors as well as their admixture, must be evaluated for the individual patient.

JACK WOOLF, M.D.

Sarburg O. and Casamajor L. Phlebotomias and Phlebothrombosis of the Brain in the Newborn and in Early Childhood. *Arch. Nerv. Psychiat.* Chic., 1944 53: 170.

The basis of this report is a rather rare condition and a controversial one. It has to do with cyst formation and softening of the brain in children shortly after birth or before birth and results in the clinical picture of dementia, spasticity and finally death. The authors wish to show that the condition is primarily due to obstruction and thrombosis in certain of the venous areas of the brain and that this con-

Fig. 1. Final state of the process.

dition results from trauma before or during birth. There is a clinical discussion of some of the literature especially the German literature on this subject, and 2 illustrative cases of their own.

The first case was that of a child seen when he was nine months old. He had been normally delivered but from birth had not been active, had not eaten well and had not taken any interest in his surroundings. At the age of four months convulsions had set in with opisthotonos. The child died at the age of nine months. The brain was then examined and it forms a basis for this discussion.

The second case was that of a child who reached the age of thirteen years before he died. He was normally delivered but when he was two and one half months old it was noted that he did not move his leg and that he had a curvature of the spine. He could not sit up nor hold up his head. Pneumonia developed when he was eighteen months old. This child was first seen in the Neurological Institute when he was about two years old. At that time he showed marked spasticity and primary optic atrophy. The condition became more and more marked until finally a stage was reached which is illustrated in the accompanying figures.

This child constitutes the second case on which the argument is based. The pathological changes in the brain were necrosis in the centrum semiovale of the brain with softening which was followed by total or partial destruction of the brain tissue and resultant cyst formation. The least resistant structures that is the myelin sheaths and the axons were first destroyed and the more resistant structures, the glia were spared until very late in the condition. In the stages of complete destruction cyst formation occurred and in incomplete destruction sclerosis. The site of the lesions corresponded to the drainage area of certain veins notably the vena cerebri magna of Galen and the area drained by the superior sagittal sinus.

The clinical picture was as follows

The children were apparently normally delivered but after a few weeks they showed signs of a disease

which ended in an excessive increase in muscular tone opisthotonos flexed arms stretched legs, clenched fists talipes equinovarus, and exaggerated reflexes. In the pathological studies of the complaint the authors were able to show evidence of venous obstruction by stasis and venous obstruction by thrombosis in the areas of drainage of the veins already described. They are quite unable however to be sure that infection did not play an important role. The condition is, apparently, analogous to swayback in lambs. The article has some very good illustrations and the argument is quite extensive and as was mentioned before it introduces many similar cases from the literature.

LORREN VERBURGH, M.D.

Raaf, J., and Kernohan, J. W.: The Relation of Abnormal Collections of Cells in the Posterior Medullary Velum of the Cerebellum to the Origin of Medulloblastoma. *Arch. Neurol. Psychiat.*, Chic. 1944 53: 163.

The germinal bud from which the external granular layer of the cerebellum arises is situated at the posterior tip of the posterior medullary velum. It normally disappears before the end of the first month of extrauterine life. One hundred sixty-one fetal and infant cerebellums were studied, and abnormal collections of cells were found only in the region of the posterior medullary velum. Of 104 cerebellums in which the posterior medullary velum was examined microscopically, 23 were found to contain abnormal collections of cells. These cells were morphologically similar to the cells of medulloblastomas. In 8 of 25 cases of medulloblastoma the site of origin was found to be the posterior medullary velum; in the other 17 cases the site of origin could not definitely be established but it also may have been the posterior medullary velum. Since the site of abnormal collections of cells and the site of origin of medulloblastomas were found in the region formerly occupied by the germinal bud, the authors think that medulloblastomas originate frequently, if not exclusively, from cell rests which occur in the region originally occupied by the germinal bud.

Meads, M., Harris, W., Samper, B. A., and Finland M.: The Treatment of Meningococcal Meningitis with Penicillin. *England J. M.* 1944 3: 509.

Because of the good results obtained with sulfonamides there have been few reports of cases of meningococcal infection treated with penicillin. The gonococcus has been studied but the studies have been mostly confined to the treatment of sulfonamide resistant gonorrhea, which almost invariably responds to penicillin in adequate doses.

This study concerns 9 cases of meningococcal meningitis admitted to the Boston City Hospital, Boston, Massachusetts, during April, 1944. The ages of the patients ranged between fourteen and fifty-eight years. Some patients were acutely ill and irrational; 1 was acutely ill and rational and 1 was

only moderately ill when first seen. The duration of the acute illness before entry ranged from one to seven days and averaged about three days. Sulfonamide determinations of the blood were made routinely on admission in order to ascertain whether previous therapy by these drugs had been undertaken. No sulfonamide was found except in the last case. Lumbar punctures were done on admission and at intervals of from twelve to twenty-four hours. Cell counts, smears and cultures of the sediment, and chemical studies of the cerebrospinal fluid were carried out routinely. Blood and throat cultures were made on admission and in some cases were repeated once or twice daily until they were negative. Cultures and smears of the spinal fluid sediment were checked from time to time. With regard to treatment, all of the cases were started on penicillin, given both intramuscularly and intraspinally immediately after the diagnosis was made. The initial spinal dose consisted of from 10,000 to 20,000 units in 10 cc. of sterile physiological saline solution to replace a similar or larger volume of spinal fluid withdrawn.

From 5,000 to 15,000 units of penicillin were then given intraspinally at twelve-hour intervals for 2 or 5 doses, and every twenty-four hours after improvement was noted bacteriologically and clinically and this dosage was continued until clinical and bacteriological recovery took place. Intramuscular therapy consisted of doses of 15,000 units every three hours in 7 cases and of doses of 10,000 units every three hours in 2 cases. The total amount of penicillin given intrathecally varied from 30,000 to 150,000 units and averaged about 75,000 units. The amount of penicillin given intramuscularly ranged from 100,000 to 1,155,000 units and averaged about 500,000 units. Very careful records were kept of the patient and there is a large table summarizing each case with dosage, bacteriological effects, and results. In 1 case a convulsion occurred eight hours after the first lumbar puncture with the introduction of penicillin. In 6 cases improvement was first observed in from one to five days after the treatment was started (the average was about three days). In 3 cases there was a clinical recurrence, 1 on the 1st day and 1 on the fourth day. In these cases penicillin therapy was discontinued and sulfonylurea therapy was substituted for it. In the case in which sulfonamide had been given before admission the patient responded rapidly after twenty-four hours of penicillin treatment. Six patients became afebrile in from five to fifteen days, the average being almost ten days. In 3 cases the response was fast. In the first of these 3 the patient was afebrile in three and one-half days; in the second, after twenty-four hours; and in the third after fifty-two hours.

The conclusion was reached from the clinical and laboratory findings in these 9 cases of meningococcal meningitis treated with calcium penicillin, that sulfonamides are the drugs of choice in the treatment of group 1 meningococcus meningitis and that penicillin may be effective in group 2 meningococcus

meningitis in the doses used but the response is less favorable than that from sulfonamide therapy. Clinical response to penicillin is slower than that to the sulfonamides. Abnormal spinal-fluid chemical and bacteriological findings persist longer there may be recurrences and finally sulfonamides may have to be resorted to to effect a cure. Calcium penicillin is very effective against group 1 meningococcus bacteremia.

Smith, A. DeF. Deery E. M., and Hagman, G. L.: Herniation of the Nucleus Pulposus. A Study of 100 Cases Treated by Operation. *J Bone Surg* 1944, 26: 821.

This study is based on 100 consecutive patients with herniation of a nucleus pulposus who were operated upon at the New York Orthopaedic Dispensary and Hospital, New York, between January 1937 and April, 1943. Low back pain to some degree was present in all but 1 patient. The results of the treatment are estimated in only 70 cases because the remainder of the cases were operated on less than one year before this report. It is the opinion of the authors that in many cases of herniation of a disc there is a deranged or unstable lumbosacral joint. They consider this important from many points of view. They believe, first that probably more fusions should be done than are being done and second that the problem is one which concerns not only the orthopedic surgeon but the neurological surgeon, and third that the best results will be obtained by co-operation between the two men.

Fusion was done by the Hibbs method in 83 cases. The indications for fusion were an unstable joint as determined by the roentgenograms with or without symptoms of back pain. The Hibbs method of fusion was employed because of the simplicity of combining it with interlaminar removal of the herniated disc.

With regard to the symptoms and physical signs there was a history of low back pain of varying duration in almost every case. The shortest history of sciatic pain was one month (2 cases) and the longest was ten years (4 cases) the others varied between these extremes. The sciatic pain was increased with coughing and sneezing in 55 cases but the results were not always recorded. There was a decreased or obliterated lumbar lordosis in 61 per cent. Raising of the straight leg was limited in only 70 per cent of the patients. The ankle jerk was definitely diminished or entirely absent in 85 cases. It was believed that the sensory changes were by far the most accurate means of discovering the site at which the herniation was to be found as neither the motor signs nor the narrowed intervertebral space, if there was one that could be seen on the roentgenograms could be relied upon to indicate the exact level of the herniation.

Air studies lipiodol studies and other similar tests are no longer used. Criteria for determining an unstable or mechanically deranged lumbosacral

joint, as seen in the roentgenograms, were numerous and included asymmetrical lateral articulations anterior or posterior displacement of the fifth lumbar body exaggeration of the lumbosacral angle a thin intervertebral disc, and a transitional or partially sacralized lumbosacral vertebra. With regard to the operation, the usual technique was employed with the exception that the patient was placed in a kneeling position with the hips flexed at 90 degrees. This was considered to be an important point in the technique of the operative procedure, especially if a fusion was to be performed. The patient was allowed up in a Taylor brace at the end of six weeks, and normal activities were usually begun about five months after the operation. Among the 83 patients who had a spinal fusion, failure occurred in 8 or about 12 per cent. However in 2 or 3 of these a good result was obtained by a secondary repair operation.

The results were classified as excellent good or poor. An excellent result was considered to have been obtained when the patient was able to return to the same occupation or one equivalent to that which he had before operation. A good result was considered to have taken place when only slight pain was felt and there was no disability. In the patients who had sufficient pain to cause partial or complete disability the result was described as poor. On this basis there were 24 excellent results 33 good and 13 poor.

ADRIEN VERBRUGHEM M.D.

Woodhall, B.: Fibrin Foam as a Hemostatic Agent in Rehabilitation Neurosurgery. *J Am. M. Ass.*, 1944, 126: 469.

Since the introduction of fibrin foam as a hemostatic agent by Ingraham and Bailey in 1944 this substance has been the subject of many examinations and its use is now past the experimental stage. It was made available to the Neurosurgical Section of the Walter Reed General Hospital, Washington D C. in the fall of 1943 and since January 1944 it has been used in a total number of 226 neurosurgical operations.

Hitherto control of hemorrhage in neurosurgery was confined to the use of silver clips the electro-surgical unit, hot cotton pledgets, and muscle clips. There are certain situations in which silver clips and the cautery cannot be used hot moist surgical patties are often ineffectual and time-consuming and muscle pledgets are by no means universally successful and often promote considerable tissue reaction. Fibrin foam on the other hand is useful in many situations and is a prompt hemostatic agent is absorbable and causes very little, if any tissue reaction. It is prepared from human fibrinogen and human thrombin and is kept in a dry state in which it appears dull white and brittle. A fairly large mass of fibrin foam is packaged sterile in a dry state and with a vial of dried human thrombin. A third vial contains 30 cc. of sterile isotonic solution of sodium chloride. At the operating table the thrombin is dissolved in the saline solution by means of vigorous

stirring. Fragments of fibrin foam are then dipped into the thrombin solution and removed and used as indicated. Pieces can be cut in accordance with the size that is desired. A piece of foam dipped in thrombin solution is removed and placed against the vessels that are bleeding and a moist cotton pledget is held against this until bleeding is arrested. This method is useful especially for venous hemorrhage and in oozing from vessels in the brain. It is not considered practical for arterial bleeding.

At the Walter Reed Hospital various types of cases were used to find out the value of fibrin foam. There were 102 cases of ruptured intervertebral discs, 86 of peripheral nerve injury, 23 of tantalum plating, 1 skull defect, 9 craniotomies for brain tumors, 5 laminectomies, and 1 acute cerebral laceration. The extradural bleeding which so often accompanies the removal of the herniated nucleus pulposus was quickly and easily controlled by means of fibrin foam. It is well known that in treatment of peripheral nerve injuries a small vessel on the perineurium may be torn and this is a situation in which neither clipping nor the electrocautery is useful. However, a small piece of fibrin foam when held against the bleeding vessel quickly stops it, and makes it possible to obtain an anastomosis of the nerve in a completely dry field. In another situation when cortical scars are being removed there is often left behind a shallow crater in which there is oozing from small blood vessels. In this case as in the other cases the

fibrin foam is placed in contact with the bleeding vessels, in the manner described, and is left in place. Fibrin foam has been found particularly useful in controlling the bleeding from the side of the pons and may accompany the complete removal of an acoustic tumor. In 1 instance the fibrin foam was used in an acute cerebral laceration caused by an explosion while the patient was welding a 50-gallon steel drum. After the small vessels of the acute cortical laceration were clipped and/or cauterized with the electrocautery there was still diffuse hemorrhage in spite of warm saline packs. This bleeding was instantly controlled by round discs of fibrin foam. Although this was an isolated experience, it appeared that fibrin foam might be of use in acute cerebral lacerations. During this time of war this information may be of considerable significance.

In all of the procedures in which the hemostatic agent was employed, the hemorrhage was controlled instantly. No clinical untoward reactions that could be attributed to the use of the fibrin foam were observed. On 2 occasions in which the wounds were re-explored an opportunity was afforded to observe possible tissue reactions from the fibrin foam, but in neither case was there any evidence that this method of hemostasis had caused any such reaction. It appears that this method of hemostasis promises a very good result for the future in war injuries involving the nervous system.

ADRIAN VERBULOGHEN, M.D.

SURGERY OF THE THORAX

TRACHEA, LUNGS, AND PLEURA

Alexander J: Roles of Medicine and Surgery in the Management of Bronchiectasis. *Ann. Int. M.* 1944, 21 565

From the point of view of treatment it is important that a distinction be made between (1) cases of bronchiectasis in which there is no obstruction of the larger bronchi (2) cases in which varying degrees of obstruction of the larger bronchi exist because of a foreign body bronchial carcinoma or adenoma, tuberculous granulation tissue or fibrous stricture in the bronchial wall, or pyogenic granulation tissue and extrabronchial pressure by enlarged lymph nodes or other tumors and (3) those relatively infrequent cases which present the characteristic symptoms of bronchiectasis but in which no bronchiectasis exists, the symptoms being due to allergic or asthmatic bronchitis or true chronic catarrhal bronchitis. The presence or absence of bronchiectasis can be determined accurately only by good bronchograms, whereas differentiation between the first and second groups mentioned in this paragraph can best be made by bronchoscopy. Although bronchograms frequently reveal even partial bronchial obstruction they do not reveal its nature.

Lobectomy is without question the treatment of choice for those patients (1) whose age, cardiorespiratory functional reserve and general condition are suitable (2) whose lesions are restricted to one lobe to the right lower and middle lobes to the left lower and lingular (left middle) lobes or in some cases to all the lobes of one lung (total pneumonectomy) to one lobe of each lung or to two lobes of one lung and one lobe of the other lung (bilateral lobectomy) and (3) who have failed to attain a satisfactorily stable condition of improvement from nonsurgical treatment. Special additional reasons for performing lobectomy in childhood are that the dangers of bronchiectasis are particularly great then and that the removal of the lesions makes probable a normally long life of health in place of a probably short life with varying degrees of illness and disability. The indications for lobectomy may become further extended in certain cases of multiple lobe bronchiectasis by the wider application of Churchill and Bellamy's suggestion that in certain cases only the affected segments of the lobes be removed. This principle has been applied for a number of years in the removal of the lingular segments of the left upper lobe, which is technically simpler and safer here than in any other lobar segment.

The present safety of pulmonary lobectomy has solved the problem of treatment for approximately half the patients with bronchiectasis but the other half are for various reasons (especially because of extensive bilateral lesions) not suitable for the operation. Nonsurgical methods of treatment, if properly

and faithfully carried out, can be made effective in greatly alleviating the distressing symptoms of the disease in a large majority of patients in spite of the pessimistic opinions about the value of nonsurgical treatment that have recently been expressed by a number of physicians.

Postural drainage is the most valuable of the non-surgical therapeutic measures. A bronchoscopy carried out immediately after a postural drainage determines the relative number of retained secretions and therefore gives an indication of the probable effectiveness of postural drainage.

Every bronchiectatic patient should have at least one bronchoscopic examination not only because some otherwise undetectable, important intrabronchial lesion may be discovered, but also because the aspiration of secretions and the chemical shrinkage of the bronchial mucosa often bring about improvement in the symptoms which in occasional cases (notably in children, but also in adults) is astonishingly great. Bronchoscopy is also of great value in preventing the development of bronchiectasis in early cases of pneumonitis or 'unresolved pneumonia'. An effective treatment, which should be immediately preceded by a postural drainage and which may occupy from fifteen to thirty minutes requires (1) that the bronchi containing secretions should be repeatedly aspirated until all free secretions have been removed (this is to be done both before and after the mucosa has been shrunken and the patient has repeatedly coughed on command) and (2) that equal parts of a 2 per cent pontocaline hydrochloride and 1 to 2,000 epinephrine solutions or other shrinkage drugs, be directly applied, step by step to all parts of the mucosa that are swollen, and that an excess of the solution in the gauze pledgets be squeezed into those bronchi of the affected parts of the lung that are too small to be directly reached by the pledgets or a small amount of the solution be injected into these bronchi.

Since the primary purpose of nonsurgical treatment is to bring about the maximal evacuation of secretion cough medicines that check the cough reflex are not helpful but harmful and measures that promote expectoration are beneficial. Such expectorants as ammonium chloride, iodides, ipecac steam inhalations, which may be medicated with benzoin or menthol and the inhalation of a nebulized spray of 1 to 100 dilution of epinephrine solution may prove useful if the secretions are thick and especially viscid and if expectoration is difficult.

Only in exceptional cases has chemotherapy proved useful. Intravenous arsenicals which are especially dangerous in patients having a prolonged suppurative disease, have occasionally reduced pulmonary infection when it was caused chiefly by the Vincent group of organisms. The sulfonamides whether given by mouth or by a nebulizer have been

disappointing in chronic bronchiectasis although an excellent effect has been produced in a few patients.

Treatment of infection in the nasal sinuses, nose, mouth, and pharynx should be given and may improve the bronchiectasis symptoms.

General hygienic measures are indicated in most cases of bronchiectasis. Ideally patients who have even mild fever and who are fatigued and under weight should be put to bed for a period of weeks or months under the sanatorium type of regimen, or should at least spend long hours in bed at night and two hours in bed after lunch. Generalized heliotherapy may be helpful as a hygienic measure, but should not be used in febrile patients or in those subject to recurrent attacks of pneumonitis. Anemia should be treated by blood transfusions if necessary.

The author found allergic desensitization disappointing.

In certain cases of bronchiectasis with repeated severe hemoptyses temporary phrenic paralysis may stop the bleeding, but this operation should not be used if the patient has difficulty in raising his bronchopulmonary secretions.

The author is opposed to induced pneumothorax, roentgen-ray therapy "the thirst cure," and the many operations that have been proposed, or used with poor results, before the operation of lobectomy was developed to its present status of safety and effectiveness.

JOSEPH K. NARAT, M.D.

Shank, P. J.: Empyema of the Lung, A Review of the Literature and an Analysis of 169 Cases. *Am. J. Surg.* 1944, 66: 224.

Empyema per se is rarely if ever a primary disease. It is most frequently secondary to pneumonia, influenza, or measles. Approximately 75 per cent of all empyema is due to the pneumococcus and 15 per cent to the streptococcus, the remaining 10 per cent is due to staphylococcus, influenza, and other rarer types of organisms.

The diagnosis of empyema depends upon a septic temperature, flatness on percussion, roentgenographic findings and the aspiration of pus from the chest. It is important that diagnosis be made early. Treatment consisting of thorough and rapid evacuation of the pus should be instituted, to spare the patient prolonged infection and complications. Frequent and early roentgenograms will produce many more early diagnoses. Roentgenograms should be made in the oblique as well as the frontal and lateral planes, as many interlobular encysted, and pulmonary abscesses may be demonstrated. Of all the diagnostic procedures, aspiration remains the definite means of diagnosis after accurate localization of the pus by the roentgenograms. The aspiration of tuberculous pus may lead to disastrous results if the condition is treated by open or closed thoracotomy. Aspiration is also important in determining the proper drainage site. In location, empyema is usually found in one of the lower lobes, but it may be multifoliated. Recognition of multiple loculation depends upon careful study of posteroanterior

lateral and oblique roentgenograms. The loci should be drained as they are recognized, either through the original or supplementary incisions.

In any treatment of pleural empyema, the objectives to be attained are the nutrition of the patient, as complete and early drainage as possible, and expansion of the lung. To be excluded are: operative shock, mediastinal flutter and chronicity. Elker and Graham have stated that the first aim should be to save lives. Secondary to this are: (1) complete evacuation of the pus (2) rapid elimination of toxicity and systemic effects (3) sterilization and subsequent complete closure of the cavity with obliteration of all foci of infection (4) complete healing of the external wound (5) restoration of the patient to his normal social and economic position (6) avoidance of chronic empyema and recurrences and (7) accomplishment of these results in as short a time as possible.

Aspiration should be used in all cases at the beginning of treatment and should be repeated before operation, to relieve mechanical embarrassment due to the accumulation of fluid in the pleural cavity and to alleviate the toxic symptoms during the synpneumonic stage. Multiple therapeutic aspirations should be done in encysted empyema and followed by the injection of air in order to outline the cavity in the roentgenogram. While the diagnosis of thoracic empyema should never be made without the introduction of a needle and the removal of pus, the treatment of empyema by multiple aspirations should not be continued after four or five aspirations unless the patient shows a marked response to the treatment.

Intercostal closed drainage is advised particularly when reamobilization of fluid after aspiration is so rapid that even daily aspirations fail to give adequate relief. Closed operations are those in which a catheter is inserted into an empyema cavity through an intercostal space without exposure of the parietal pleura. It is believed that no form of closed drainage stays absolutely airtight for more than a week or two. Airtight drainage for more than two or three weeks is rarely necessary. It should not be continued longer than this unless there is improvement shown by the clinical condition with a decrease in the size of the cavity and re-expansion of the involved lung. If a week or two of intercostal closed drainage does not prove adequate, especially in the pneumococcal type of infection, the patient's condition should be improved sufficiently to warrant open surgical drainage.

In properly selected cases, open drainage is one of the most efficient methods of treating empyema, since it allows exploration of the pleural cavity for the identification of bronchial fistulas and possibly accessory empyema pockets, and permits complete removal of all fibrin masses and the proper placement of the tube.

Patients with thoracic empyema, having a reduced vital capacity are in a state of air hunger a greater part of the time, hence the anesthetic that gives the

least pulmonary embarrassment should be selected. It must (1) avoid reducing the vital capacity below the level to which the patient has become accustomed during his illness. (2) allow the lateral position of the patient on the operating table on his sound side. (3) prevent loss of blood as the thoracic wall is a very vascular bed and (4) deal with the copious amount of sputum. Diagnostic and therapeutic aspirations can all be performed following the local infiltration of novocaine or of one of its derivatives. Rib resections can be done under local anesthesia but some patients object to the cutting of the rib and a general anesthetic must be given. Ethylene is a good general anesthetic and seems to meet all requirements. It has the added advantage of allowing a higher intake of oxygen. Cyclopropane maintains the highest percentage of oxygen in the circulating blood which factor is so important in patients with a reduced vital capacity. Unfortunately in a certain percentage of patients who have cardiac lesions, cyclopropane is contraindicated and may prove fatal by producing ventricular fibrillation. Positive-pressure anesthesia should be used when the pleural cavity is opened. Endotracheal anesthesia and suction must be employed in the presence of copious amounts of sputum.

The postoperative treatment of thoracic empyema, particularly in children is of paramount importance, for on it depends the rapid and complete recovery of the patient. Adherence to minute details is mandatory to prevent too early closure of the cavity and a resultant chronic infection. Physical examination of the chest is of little value. Frequent estimations of the capacity of the cavity along with frequent roentgenograms are the only accurate method of determining progress of the disease. Following the evacuation of the pus and the receding in size of the empyema cavity the re-expansion of the lung is followed closely. Blow bottles have long been used to aid and increase the speed of re-expansion of the lung and of reduction in size of the cavity. It is difficult even now to make any final remarks on the efficiency of the sulfonamide drugs in the treatment of pneumonia, since there are so many variable factors in its treatment. A few facts of significance have emerged namely sulfanilamide does not produce any dramatic change in the course of hemolytic streptococcal pneumonia and it does not seem to reduce the incidence of empyema. Lastly but most important in the postoperative care, is maintenance of the patient's nutrition. He should receive a well balanced high caloric, high vitamin diet. The loss of plasma proteins from the large, raw necrotic area of the pleural abscess cavity may be compared to the loss of plasma proteins from a burn of like size and must be replaced by transfusions of plasma as well as of whole blood.

Empyema complications result in most instances from long delayed treatment. If not drained surgically the pus may burrow in many directions and cause perforation into a bronchus or empyema necessitatis or perforation into the trachea, esophagus,

pericardium blood vessels, or mediastinum. Occasionally it may penetrate the diaphragm to the peritoneal cavity or to the extraperitoneal region. Transdiaphragmatic and retrodiaphragmatic extension of infections may occur. Infections of the chest wall are not regarded as serious complications and are rather infrequent. Scoliosis is a complication of empyema which varies directly with the duration of the empyema and inversely with the patient's age.

A proper understanding of the pathology and pathological physiology of acute empyema and its application to the treatment of the disease would render chronic nontuberculous empyema a clinical rarity. If there is evidence of a considerable cavity four or five weeks after drainage of the purulent exudate and if the tissues are not well healed about the tube it is well to do a secondary rib resection and remove the rib above or below the original drainage. This also holds true for any secondary abscess draining into the main empyema cavity. Hindrance of the free outflow of the discharge in a secondary cavity results in more invasion of the wall and more protective response from the surrounding tissue. Chronic empyema implies attenuated infection such as might readily occur with an intermittent discharge slightly slower than the accumulation or with an undrained discharge. The essential cause is granulation tissue which replaces the pleura under repeated infection. Another cause fortunately not common is the presence of foreign bodies in the pleural cavity. In the treatment of chronic empyema the more conservative method should be given a fair trial before more mutilating ones are attempted. Carter lists the three classes of chronic empyema requiring surgery as follows: (1) secondary tuberculous empyema, (2) pyogenic empyema of several years duration and (3) chronic empyema with bronchial fistula. Three unroofing operations of short duration are preferable to one prolonged one. Empyema cavities decrease remarkably in size from one stage to the next so that the ultimate amount of rib removal is less for the operation in stages.

Putrid empyema is a pathological entity deserving separate consideration. Effective treatment depends upon thorough knowledge of its pathogenesis, pathology and clinical manifestations. The contents of a putrid empyema abscess cavity consist of foul pus and detritus gathered in one or more compartments. Following disclosure of foul pus or foul air operation should be performed immediately since nothing can be gained by delay and after the aspiration of foul pus there is a possibility of the development of putrid phlegmon in the chest wall. This usually dissects between the ribs and intercostal muscles and may not be recognized for several days. Immediate improvement is seen after evacuation, ventilation and aeration of an anaerobic infection. Wide unroofing allowing full visualization of the cavity is imperative in order that drainage may be maintained to the bronchial fistula and for better drainage of the pulmonary abscess. Rib resection should be just short of the limits of the lesion to prevent entry

into the uninvolved portion of the pleural space. The cavity and all its recesses are then packed with iodoform gauze or zinc peroxide. Closed drainage is justified in putrid empyema only because of the danger of open operation when the mediastinum is mobile. A basic objection to closed drainage is its inability to eradicate the anaerobic infection without free ventilation. The mortality rate need not be high if there are early recognition, accurate diagnosis and immediate treatment. Immediate open drainage gives the best results. All less radical methods give unreasonably high mortality rates.

The results in these 169 cases of nontuberculous thoracic empyema with 11 deaths are quite comparable to those in other recently reported series. The mortality rate of 6.5 per cent is recorded. The cases have been divided into two groups for study, one group comprises those patients twelve years of age and under and the second group those over twelve years of age. The cases have been studied in three five year series. There is very little difference in the mortality rate for these periods except in the last five year period when the mortality rate for putrid empyema increased to 40 per cent. One hundred and five males and 64 females had thoracic empyema. There were 83 cases with involvement on the right side and 83 with involvement on the left side. Four patients had both sides involved. The pneumococcus which was the most frequent organism found, was responsible for 73 per cent of the cases of thoracic empyema, the streptococcus for 20 per cent and the staphylococcus for 3 per cent. The other types of organisms were responsible for the remaining cases of empyema. There were 9 cases of putrid empyema. Otitis media was the most frequent complication and associated condition. Treatment consisted of various operative procedures. Aspiration with subsequent rib resection and open drainage was carried out 91 times. Thirty-seven patients were subjected to aspiration and closed intercostal drainage followed by open rib resection. Sulfonamide therapy was used on some patients mostly by the family physician before they arrived at the hospital and it is difficult to evaluate the results. It has a beneficial effect in lowering the mortality rate, but it has not appreciably altered the development of empyema. CHARLES BARON, M.D.

HEART AND PERICARDIUM

Neuhof, H.: Indications for Pericardiectomy with Special Reference to the Exposure of an Infected Patent Ductus. *J. Thorac. Surg.* 944, 3 374.

In addition to the four standard indications for pericardiectomy with or without drainage, (hemopericardium, suppurative and constrictive pericarditis, foreign bodies, and neoplasms) seven further conditions in the author's experience are described with illustrative case histories, in the hope that other surgeons will join in broadening the indications for the procedure.

The first condition was that of neoplastic disease of the left lung, in which extensive adhesions to the parietes posteriorly rendered informative palpation of the posterior aspect of the hilus impossible. Pericardiectomy with palpation within revealed involvement of the nodes at the hilus and the inoperable character of the lesion.

In another case a pericardiectomy was performed to relieve the cardiac tamponade effect of a serous pericardial effusion during anesthesia in operation for tumor of the left lung. Exploration within the pericardial sac itself disclosed the inoperable character of the lesion.

A third patient was operated upon for a pulmonary neoplasm. The lesion appeared at first to be inoperable because of fixation at the mediastinum and invasion of the pericardium, but exploratory pericardiectomy revealed the extent of the invasion. Liberal sacrifice of the pericardium made possible an adequate excision of the tumor. In order to cover the large pericardial defect, the pulmonary tissue adjacent to the stump was approximated to the mediastinal tissues medial to and above the pericardial defect.

A fourth instance was that of a twenty-three-year-old man, with a history of abdominal distention for three months. On admission his abdomen was tense with fluid and the blood pressure was 116/96, the venous pressure 19 cm. At operation the pericardium was apparently not thickened but it was somewhat opaque (restrictive pericarditis). Cardiac pulsations were normal. When the pericardium was incised it was found to be very slightly thickened. The lesion was an adhesive fibrous one of the visceral pericardium. Visceral membrane was generously removed. The freedom from aortic subaortitis (four years since operation) seems to suggest pericardiectomy in such cases, even in the presence of a pericardial sac which appears to be normal externally.

Another instance in which pericardiectomy seems indicated is when a patient does react well following initial pericardiectomy for the drainage of a suppurative pericarditis in which cases undrained collections of pus are usually found at autopsy or when the pericarditis does not clear up satisfactorily and a rather profuse discharge of pus continues from the wound. An instance of the latter type occurred in a boy of five years who had been operated upon several weeks previously. The author again widely exposed the pericardium extrapleurally and carefully incised the sac without preliminary aspiration. Purulent exudate was encountered.

The sixth condition in the author's experience in which he believes pericardiectomy is indicated is that of acute pericarditis of low grade virulence. In a woman of sixty-eight years, he explored the pleural cavity for the cause of an unexplained fever as the roentgenograms had been difficult to interpret, the pericardium, which appeared congested and possibly thickened, was aspirated and turbid yellow fluid was recovered. The culture was later reported

as sterile. The pericardial sac was laid open freely and found to be occupied by fibrinous exudate and small pools of yellowish fluid. The report on the specimen from the pericardium was acute inflammation. No organisms were found in the sections.

The last in the author's series of indications for pericardiectomy is a case of subacute endarteritis complicating a patent ductus arteriosus in which it was thought that the exposure of the ductus for ligation, especially of its posterior not easily attainable aspect, might be facilitated by incision of the pericardium and retraction of the dilated pulmonary artery. This procedure was tried in a woman of thirty years in whom the blood culture was positive for the streptococcus viridans. At operation the mediastinal pleura was incised in the customary manner and the recurrent nerve was visualized beneath the aorta. It soon became evident that dissection under vision would not be possible on the deep surface of the short, extremely wide duct. The pericardium was incised radially and freely over the region of the left auricular appendage, the incision prolonged to the beginning of the ductus and the pulmonary artery was drawn downward and medially. The deep surface of the ductus was visualized and its dissection readily accomplished.

In the discussion HARRINGTON intimated that he does not need to do a pericardiectomy in his patients with a patent ductus because he always obtains adequate exposure through a posterolateral incision which he described quite fully.

JONES cited Gross' objection to opening the pericardium when mobilizing the ductus arteriosus because the trickle of fluid from the sac obscures the field of operation and stated that he himself has not seen a noninfected ductus arteriosus which required the opening of the pericardium for ligation.

HAGERT described a personal experience with herniation of the heart through a large unclosed pericardial opening, which may be combated by turning the patient on or toward the contralateral side.

GRAHAM credited Sauerbruch with first describing the procedure of leaving the pericardium open for drainage into the pleural cavity as in cases of intractable pericardial effusion, and he described a personal experience of this nature.

HEAD described an accident tearing open of the left auricular appendage, incident to the opening and closing of the pericardium. The hemorrhage was finally mastered by grasping the entire appendage with an ovum forceps and ligating it back of the forceps. (The patient made an uneventful recovery except for two or three weeks when he had almost daily attacks of paroxysmal tachycardia.)

DOLLEY said that he believed that some type of drainage with rubber tissue to the outside or into the pleural cavity in cases in which a considerable quantity of serum is likely to form in or in the cavities of the opened pericardium is a necessary safeguard against postoperative cardiac tamponade.

JOHN W. BRENNAN, M.D.

ESOPHAGUS AND MEDIASTINUM

Daniel R. A., Jr.: Congenital Atresia of the Esophagus with Tracheoesophageal Fistula. *Ann. Surg.* 1944, 120: 764.

In the past three years 7 infants with congenital atresia of the esophagus have been admitted to the Vanderbilt University Hospital, Nashville, Tennessee. All of the patients were operated upon and 1 is living at the age of six months.

The successful case was that of a male infant born at term. Thirty-six hours after birth it was noted that the child had an unusually large amount of mucus. At fifty-six hours the diagnosis was suspected and proved with x rays. Operation was performed eighty-four hours after birth. A left posterior extrapleural approach was made under local anesthesia. The blind pouch was isolated and controlled with a silk suture. The lower end connected with the carina. A catheter was inserted through the nose and passed out of the blind loop through a small incision made in the lower end. The lower segment was doubly ligated and separated from the carina. The catheter was inserted into it below the ligature. Silk sutures were used to anastomose the upper end with the lower end below the ligature. The wound was closed and traction applied to the catheter. Gastrostomy was performed seven days later because the catheter became obstructed. Three weeks after the gastrostomy the catheter was removed and dilatations were begun and have been continued at weekly intervals.

The fistula should be exposed and ligated in all cases. An anastomosis is then attempted. In some patients it will not be possible to make the anastomosis. In these cases the upper end is brought out in the neck and a gastrostomy performed.

MISCELLANEOUS

Goldman, A.: Aerial Evacuation of the Thoracic Wounded; Consideration of Effects of Altitude. *U. S. War Med. Bull.* 1944, 43: 685.

Aerial evacuation of the wounded from combat areas has become a common practice in this war. No medical problems have been confronted except in the care of wounds of air-containing organs. In order to determine the effect of aerial evacuation in chest injuries, the author studied 30 such patients. The advantages of air transport were found to be the shortened travel time, a smooth trip, ease of loading and minimal handling. It is possible in the South Pacific area to fly at altitudes of 500 feet, and heights of over 3,000 feet are avoided. Higher altitudes can produce emergencies. All pleuropulmonary wounds are associated with varying degrees of cardiorespiratory disturbance. Altitude tends to increase that disturbance, but significant changes due to altitude are not likely to occur under heights of 3,000 feet. Air entrapped in the body is affected by altitude according to Boyle's law, which states

that the volume of any gas varies inversely with the pressure, provided the absolute temperature remains constant. Lovelace and Hinshaw state that the increase of altitude has the effect of producing considerable increase of either the volume of air in the freely expanding pneumothorax or the positive pressure within the pneumothorax if expansion is restricted. Table I demonstrates the relative volume of gas entrapped in the body at various altitudes.

TABLE I.—GAS ENTRAPPED IN BODY

Volume of gas	Altitude in feet	Barometric pressure mm. Hg.
1.0	0	760
1.2	5,000	63
1.3	10,000	53
1.9	5,000	43
2.4	20,000	35
3.0	5,000	28
4.0	30,000	20
5.4	35,000	16
7.6	40,000	14
8.8	45,000	12

A freely expanding pneumothorax simply expands at higher altitudes, and the amount of expansion can be calculated from this table. In the case of a nonexpanding pneumothorax the positive pressure becomes higher with ascent, and marked pain and dyspnea may occur. This is particularly dangerous since it may cause rupture of adhesions. A closed tension pneumothorax should be decompressed by aspiration or in an emergency by converting it into an open pneumothorax. A sucking wound is best treated by converting it into a closed pneumothorax, and aspirating. Mediastinal and subcutaneous emphysema offers hazards since the entrapped air will also expand and may cause severe obstruction to the contiguous structures. Air entrapped in the pericardium may expand to the extent of causing tamponade. In the case of diaphragmatic hernia the expansion of gas in the stomach and bowel decreases the pulmonary volume and may cause strangulation of the bowel.

Since the weather conditions, mountains and enemy action may force ambulance planes to high altitudes, the flight surgeon should have the equipment and training to manage any emergencies that may occur. If this is done air evacuation offers many advantages. Transportation is usually delayed until pleuropulmonary wounds are stabilized because most severe fresh injuries demonstrate dyspnea, shock, pain, and fear.

THOMAS F. THORNTON, JR., M.D.

Ritvo, M., and Peterson O. S. Jr.: Parasternal Diaphragmatic Hernia. *Am J Roentg* 1944, 53: 399.

Diaphragmatic hernia is defined as the protrusion of any abdominal viscus into the thoracic cavity through an opening in the diaphragm. The following classification of types is suggested:

A. Nontraumatic

1. Congenital
 - a. Esophageal hiatus
 - b. Pleuroperitoneal foramen of Bochdalek
 - c. Dome of diaphragm
 - d. Foramen of Morgagni
 - e. Absence of a portion of the diaphragm
2. Acquired
 - a. Esophageal hiatus
 - b. Pleuroperitoneal foramen
 - c. Foramen of Morgagni

B. Traumatic

1. Blows to abdomen
2. Penetrating wounds
3. Perforation of subphrenic abscess or empyema

Three groups of muscles fuse into a central tendon to form the diaphragm. These muscles arise from the sternum, ribs and lumbocostal arches. Lack of fusion of the sternal and costal muscles forms the so-called foramen of Morgagni with the development of the parasternal diaphragmatic hernia, which is the basis of the present discussion. This type of hernia is exceedingly rare although it was first recognized by Morgagni in 1769. By 1939, a total of 15 cases had been recorded in the literature.

These hernias occur more frequently on the right side because of the more extensive attachment of the pericardium to the left anterior chest than to the right. The contents of the hernia usually compress the omentum and transverse colon. For this reason the barium enema is used in the usual diagnostic roentgen study. The symptoms are usually constipation and pain in the chest, but many hernias cause no symptoms.

X-rays show a density over the lower portion of the right lung field. If the colon is present in the hernia gas may be observed. Barium studies of the stomach usually show no abnormality but varying degrees of displacement of the colon may be visualized.

In the past treatment has been conservative in most instances unless strangulation had occurred.

THOMAS F. THORNTON, JR., M.D.

Holmes, H. R.: A Case of Patent Ductus Arteriosus Associated with Multiple Pulmonary Aneurysms and Infective Endocarditis. *Br J Radiol*, 1944, 17: 374.

The author records a case of patent ductus arteriosus in which there was subacute bacterial endocarditis and multiple aneurysms of the larger branches of the pulmonary artery. The clinical description, roentgenological findings, differential diagnosis, and postmortem findings are given with a discussion.

Ligature of the patent ductus was followed by cessation of the murmur; however, two days later the patient died immediately after a copious hemoptysis.

Left and right anterior oblique films with barium confirmed the findings in the posteroanterior film and showed the absence of auricular enlargement, an apparently normal aorta, and slight enlargement of

the left ventricle. From the changes seen in forced expiration and inspiration films, it was considered that the bilateral radiating opacities were probably caused by pulmonary arterial branches and their local dilatations due to possible aneurysms. The presence of congenital rib anomalies suggested that an associated congenital cardiac lesion might be responsible, in part at least, for the abnormal shadow.

Patent ductus arteriosus is more frequently associated with other cardiovascular anomalies, and there is a known variance in the clinical signs and x-ray appearances. Therefore full roentgenological investigations are essential in the clinical assessment of the indications for timely surgery in the cure of patent ductus arteriosus.

ERIC C. ROBINSON, M.D.

Wolpaw S. E., Higley C. S., and Hauser H. Intrathoracic Hodgkin's Disease. *Am. J. Roentg.*, 1944, 52: 374.

The typical peripheral manifestations of Hodgkin's disease are well known, but the internal disorders, particularly intrathoracic manifestations, are less well recognized. This study includes 55 cases of which 35 (63 per cent) showed intrathoracic involvement. The various types of intrathoracic Hodgkin's disease are (1) mediastinal, (2) parenchymal, (3) pleural, (4) osseous, and (5) cardiac.

The mediastinal variety was the most common in this series since 50 per cent of the cases were in this group. Any of the lymph-node structures in the mediastinum may be involved, but in most cases

localized enlargement of the hilar nodes is present. Occasionally involvement is diffuse.

The parenchymal type occurred in 40 per cent of the series and presented the most confusing diagnostic problems because it varies so much and can easily be mistaken for almost any other type of pulmonary disease. Particularly common is an infiltrative lesion that can easily be mistaken for bronchogenic carcinoma. Nodular lesions are uncommon and simulate metastatic tumors. Peribronchial and bronchial invasion may produce atelectasis like that seen in primary lung tumors. Cavitation occasionally occurs when there is necrosis of tissue with extrusion through the tracheobronchial tree. Tuberculous abscess or cavitory bronchogenic carcinoma may be suspected.

Pleural involvement is quite frequent and usually takes the form of multiple nodules that produce massive effusions which can be confused with tuberculous or carcinoma. The ribs and sternum may show involvement primary or secondary to the lung. The osseous lesion is usually osteolytic. The cardiac type is extremely rare and usually secondary to mediastinal or parenchymal involvement.

Twenty three of the 35 cases were treated by irradiation. Seventeen cases considered to be adequately irradiated showed definite favorable responses of varying degrees. Three patients with adequate, and 2 patients with inadequate dosage showed no favorable response and in 1 case the result was not recorded. The technical aspects of roentgen therapy are discussed.

Fig. 3. Two islands of so-called intestinal epithelium.

develops on the basis of gastritis usually hold the theory that it is an atrophic gastritis.

In answer to Crohn's statements MEISSNER asserts again that he has found marked epithelial changes in severe gastritis and believes that they were strictly comparable to well accepted precancerous lesions elsewhere and that it is on this basis only that it is believed reasonable to expect that carcinoma may develop in the stomach from this change.

JOHN W. BRIDGMAN, M.D.

Blagard, J. D., and Overmiller W: Emergency Gastroectomy for Acute Perforation of Carcinoma of the Stomach with Diffuse Soiling of the Free Peritoneal Cavity *Ann Surg* 1944, 120: 326.

Acute perforation of carcinoma of the stomach into the free peritoneal cavity occurs infrequently. It is usually unanticipated and in many instances the malignant character of the perforated ulcer is unrecognized with the result that the case is managed as a benign lesion and treated as such. Routine frozen-section examination of a biopsy from the edge of all gastric perforations would reveal the presence of a neoplasm. Any surgical treatment short of resection in the resectable cases is of doubtful value. But there is the question whether resection be performed as an emergency gastroectomy in the presence of diffuse soiling of the peritoneum or whether it be reserved for a secondary operation contingent upon recovery from the primary operation of simple closure of the perforation.

Because this and other questions relating to this entity can be answered only by the accumulation of many isolated individual experiences it seemed justifiable to the authors to record their experience with a single case and to add a statistical compilation of the reported cases to date. A case report is described in detail. They have collected a series of 217 cases, in which the diagnosis has been established at operation or postmortem examination. In half of these cases no operation had been performed. In only 7 of the 217 cases was it alleged that a correct

diagnosis had been made prior to operation or post mortem examination.

The failure to recognize the presence of carcinoma suggests that the majority of carcinomas which perforate are small and relatively confined lesions, presumably suitable for resection, a premise which is borne out at the autopsy table. In these cases there is, therefore the possibility of considerable salvage of life. Approximately 50 per cent of carcinomas which perforate are otherwise resectable upon the basis of generally accepted standards. For resectable lesions emergency primary gastroectomy is the operation of choice. The results of operative procedures in 115 cases of perforated gastric carcinoma are listed in a table, under procedure, recoveries, and hospital deaths.

EARL C. ROWMAN, M.D.

Rafsky H. A., Katz, H., and Krieger C. L: Varied Clinical Manifestations of Lymphosarcoma of the Stomach. *Gastroenterology* 1944, 1: 297.

This study is based on a series of 12 patients of whom 7 were males and 5 females. Their ages ranged from nineteen to eighty years. All of the patients came to operation. The symptoms of the patients covered a period of from four weeks to three years, with more or less gradual onset, the complaints differing from those of ulcer or perhaps resembling them but on the whole there was no characteristic or typical history to indicate the presence of the disease, nor did the physical examination reveal it. The patients appeared to be chronically ill but did not, as a rule, appear to be undernourished. Thirty three per cent revealed a tumor mass in the abdomen. Roentgenography resulted in a definite diagnosis of lymphosarcoma of the stomach in 4 (33 per cent) and suspicion of neoplastic disease in 6 (50 per cent).

When x ray findings are obtainable they may be grouped as follows: (1) a filling defect with smooth margins; (2) a localized type of filling defect, rounded and smooth when the body of the stomach is involved, and annular when it occurs at the pylorus; (3) a diffuse type of defect involving a large portion of the stomach and simulating carcinoma or fibrous plastica; (4) a defect with the pattern of giant rugae; (5) in the late stages the walls may be somewhat rigid, due to infiltration and yet peristalsis may be sluggish or irregular; (6) gastric retention, which is an uncommon finding; and (7) changes in the size of the stomach.

Gastroscopic findings were not as characteristic of malignancy as those seen in carcinoma of the stomach. Endoscopically in 4 patients there was a marked hypertrophy of the rugal folds and the mucous membrane appeared to be intact although it was somewhat swollen and edematous. The entire gastroscopic field presented a stiffened appearance. Late in the disease flattened ulcerated areas on the crests of the folds were seen. Even at operation, with the surgeon palpating the stomach in the open abdomen, the condition could not always be detected, although later microscopic examination of the resected stomach revealed in some cases that it was involved.

The latest reports on the x ray treatment of lymphosarcoma of the stomach are very encouraging of the 2 types retic lum-cell sarcoma and the small round-cell lymphoma the first gave a less favorable response in treatment.

The details of several illustrative cases are included

JOHN W. BRENNAN, M.D.

McKlitrick, L. S., Moore, F. D. and Warren, R.: Complications and Mortality in Subtotal Gastrectomy for Duodenal Ulcer; Report of a Two-Stage Procedure. *Ann. Surg.* 1944, 120: 531

In this article the hospital morbidity and mortality in 175 subtotal resections done in the period from 1936 to 1941 are analyzed and contrasted with the results in 145 resections done in 1942 and 1943. As one of the many factors producing improvement in the second group a technique for the performance of subtotal gastrectomy in two stages is described. Of the 175 subtotal resections of the stomach (from 1936 through 1941) 55 were performed for gastric ulcer with no deaths. One hundred and twenty four operations were undertaken for duodenal ulcer with 10 deaths a mortality of 8.1 per cent. The various types of operations are shown in a table. The 124 cases of duodenal ulcer were carefully studied from the point of view of fatal and nonfatal complications and the results of this study are grouped in another table.

The experience of the authors suggested that the duodenal stump and its management played an important role in the morbidity and mortality following subtotal resection for duodenal ulcer. In 7 of their 10 fatal cases the infection arose from the duodenal stump. The resection for exclusion as conceived by Finsterer seemed to them to represent the ideal first step of a two-stage procedure, having as its objective the safe removal of the entire lower two-thirds of the stomach. It was anticipated that after from six to twelve weeks had elapsed the inflammatory process around the duodenum would subside, the ulcer probably would heal, and excision of the antral segment could then be safely undertaken. This procedure has now been carried out in 37 cases. It is the authors' opinion that the two-stage gastrectomy will find usefulness for the skilled and experienced gastric surgeon in occasional cases in which the inflammatory fixation of the pylorus and duodenum destroys landmarks and renders adequate duodenal closure difficult or impossible. The operative technique is described in detail and is well illustrated. Complications of the two-stage procedure are enumerated. The answer to the question: Must the antrum always be removed? is an unqualified "yes." This conclusion is based upon three considerations:

1. Edkin's work demonstrating that a substance in the antral mucosa when injected intravenously in dogs, produces a massive gastric secretion even in isolated gastric tissue.

2. The fact that 9 patients known to the authors one of them in this series developed jejunal ulcers

when the antrum was left in for from three to thirty six months after a Finsterer type of procedure.

3. The fact that all of these patients have had their jejunal ulcer cured by antral excision alone or in combination with a higher resection.

During the last two years there has been an improvement in the results in these cases the most important factor in the authors' opinion being the almost complete elimination of those complications secondary to leakage or contamination from the duodenal stump.

EMIL C. ROBITZKE, M.D.

Milpriss, T. W., and Etheridge, F. G.: Chest Complications after Gastric Surgery. *Brit. M. J.* 1944, 2: 466

The authors call attention to the frequency the importance, and the severity of postoperative pulmonary complications in gastric surgery. A report is given of such conditions in 100 consecutive cases. For a correct appraisal of this incidence, some information regarding the condition for which operation was indicated in each instance is necessary. The operative mortality too must be considered, as well as the standards by which the pulmonary complications have been assessed.

Gastrectomy is more difficult when it is done for a peptic ulcer for which a previous operation was performed. Moreover greater difficulties are involved when a bleeding ulcer or a malignancy is present. Accordingly the cases considered are classified as follows: (1) patients with peptic ulcer who had not previously undergone surgery apart from the suture of a perforation (78 patients: 1 fatality); (2) patients who had previously undergone surgery (11 patients: 2 fatalities); (3) patients with complications such as acute hemorrhage (5 patients: 1 fatality); and (4) patients with carcinoma of the stomach (6 patients: no fatalities). From this it will be seen that gastrectomy was performed for the usual indications. Of the 100 patients 4 died.

Physical examination of the chest was routine during the first two or three postoperative days. Any abnormal rise in temperature, pulse or respiration rate suggesting the possibility of a pulmonary complication called for roentgenography. Of the 100 patients, 45 were subjected to roentgenography within the first few days after operation.

Among the primary types of immediate pulmonary complications found are (1) bronchitis (2) lobar atelectasis and (3) lobular or patchy atelectasis. The authors diagnosed bronchitis in patients who had a productive cough with moist sounds in the lungs even though x ray examination showed no abnormality. Lobar atelectasis implies an involvement of one or more lobes a condition which is easily demonstrated by roentgenography. The authors found lobular or patchy atelectasis the most common complication. In most cases physical examination showed that the lower part of the chest on one or both sides was expanding somewhat less fully than normal and auscultation revealed a poor air entry with some adventitious sounds. There would be a

The pathological changes accompanying Meckel's diverticulum depend to a large extent on the anatomic deformities present. These are also briefly mentioned and discussed although the ones most commonly found may be grouped into three categories namely (1) inflammatory type (2) peptic-ulcer type (with or without hemorrhage) and (3) intestinal obstruction type (with or without intussusception). It would appear that another phase of the peptic ulcer type is being seen and not being recognized. This the author believes is the group of diverticula that contain heterotopic gastric mucosa and which, when examined, show no evidence of inflammation or other disease. This condition might be called dyspepsia Meckeli and probably represents a preulcerative condition in the diverticulum or in the marginal portion of the ileum. The best classification is probably that of Greenblatt and his coworkers.

The symptoms and signs that occur from Meckel's diverticulum depend to a great degree on the anatomic disposition of the tissues and the pathological changes involved in the diverticulum. These factors are extremely variable. The signs and symptoms fall into three groups and are described. The treatment of Meckel's diverticulum is surgical, with excision of the diverticulum. Twelve case reports are cited.

EMIL C. ROSENBERG, M.D.

Berger L., and Mirach E.: Bowel Surgery Impressions after 10 Years of Experience. *Am. J. Surg.* 944 66 31

The data and impressions submitted in this report have been derived from a service of eight beds over a five year period. There were a total of 116 patients with disease of the large bowel, of which 12 had chronic ulcerative colitis and 22 had malignancy of the right colon, 10 of the midcolon, 43 of the left colon, and 41 of the rectum, while of the remaining 63 had volvulus, 3 diverticulitis of the sigmoid, and 1 imperforate anus. The diagnosis was based on the symptomatology, the contrast enema and sigmoidoscopy.

"The limits of operability have been extended to the point that only if the bowel is frozen, or the liver studded, is a palliative operation performed. Lymphatic metastases ranked high in all groups of colon cases, varying from 44 to 68 per cent, while vascular metastases varied from 22 to 30 per cent. Emphasis was placed upon the fact that the presence of distant metastases, especially in the liver, did not preclude resection of the local growth. Operability was further influenced to a marked degree by the presence or absence of obstruction. The deaths from acute obstruction occurred solely in those patients with obstruction in the left colon, mainly in the splenic flexure. In this group, with marked obstructive symptoms, death was the rule even though minimal decompressive procedures were utilized. Medical decompression with a Miller Abbott tube was not successful in these acute cases. Cecostomy was preferred to transverse colostomy. In addition

the subacutely obstructed cases which responded to medical decompression and were clinically so improved that no obstructive symptoms were manifested showed dilated loops of bowel at operation. When radical surgery was attempted in this group, the mortality was high and the convalescence very stormy. The lessons learned from this group of patients were that it was better to perform minor preliminary decompressive procedures rather than immediate radical resection, and that operability for the most part depends on whether the patient's bowels are not obstructed plus the intra-abdominal findings.

Preoperative blood transfusions to restore hemoglobin to 70 per cent, plasma transfusions, parenteral amino acids, and additional protein feedings were used to elevate the serum protein to a minimum level of 6 gm. Low blood-chloride levels were also corrected. Determinations of the blood-sugar level were routinely made in all patients with the remark that diabetes was discovered several times in cases in which it had been totally unsuspected. Elevated urea nitrogen is in itself not a contraindication to operation, but its presence almost invariably suggests a stormy postoperative course. Prostatic hypertrophy with chronic urinary obstruction was investigated and if present was treated by staged or transurethral prostatic resection before the major bowel surgery. Various attempts were made to cleanse the bowel and reduce the bacterial flora and fauna of the intestinal tract in uncomplicated cases. The routine at present used consists of (a) preliminary purgation, followed by (b) sodium sulfathiazole. No mechanical cleansing of the bowel was performed. The authors have noted that when they used either sulfanilamide or sulfadiazine spinal anesthesia with procaine was not effective in the usual doses or it was completely ineffective.

Shock was treated prophylactically by routine 1,000 cc. blood transfusions during and immediately after operation.

With the authors' meticulous preoperative rehabilitation of the patients, one-stage procedures became justified in most cases. Anesthesia as individualized to each patient but whenever possible spinal anesthesia was the method of choice. However, colostomy closures were performed under inhalation anesthesia because cleanliness of even the posterior spinal region is always suspect in the presence of an open functioning colostomy.

Of 23 patients with lesions of the right colon, 12 were operable. There were 5 one-stage hemicolectomies with ileotransverse colostomies with 1 death, and 7 Laseky right hemicolectomies with 1 death. In lesions of the midcolon, the operation of choice was a Rankin obstructive resection. Ten patients with this condition were treated and 9 were resectable with no mortality. Carcinoma of the left colon was also treated by a Rankin obstructive resection with delayed establishment of colonic continuity. There were 43 cases of carcinoma of the left colon, 9 of the splenic flexure, 8 of the descending colon, and 26 of the sigmoid. Thirty were operable

with a mortality of 10 per cent. The operation of choice in carcinoma of the rectum was a one-stage combined abdominoperineal amputation of Miles. Eighteen of these patients had a one-stage combined abdominoperineal amputation with 1 death. Ten had a first-stage Lahey procedure. Of this group only 5 returned for the second stage, with 3 deaths. Eleven patients were inoperable and had only palliative colostomies. SAMUEL J. FOOLSON, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Armstrong, C. D., and Carnes, W. H.: Obstruction of the Hepatic Veins (Chiari's Disease). Report of 5 Cases. *Am. J. M. Sc.* 1944, 208, 470.

The authors report 5 cases of a rare disease, hepatic vein thrombosis. Almost 60 cases had been reported. The thrombosis occurs most frequently where the hepatic veins empty into the inferior vena cava, probably because of eddy currents formed at the oblique entering angle. As thrombosis of the hepatic vein is often accompanied by inflammatory changes in the inferior vena cava, it is probable that the two processes are continuous. Hepatic vein thrombosis may be partial or complete, or complete with recanalization. Postmortem examinations reveal a characteristic central necrosis of the liver lobules, congestion of blood in this locality, replacement fibrosis of the liver and splenic enlargement.

Obstruction of the hepatic veins has been equally distributed between males and females. The youngest person was seventeen months and the oldest seventy years of age. It occurs most frequently between the ages of twenty and forty years. It may occur in the acute or chronic form.

Pain over the liver sometimes radiating to the back and shoulders, rapid accumulation of ascites resistant to diuretics, simultaneous enlargement of a smooth-edged liver and spleen, development of a collateral circulation, and edema of the legs suggest obstruction of the hepatic veins. This condition is rarely diagnosed during life as the clinical picture is that of obstruction of the portal vein and hepatic insufficiency.

The authors found 5 instances of hepatic vein obstruction in 11,979 autopsies, an incidence of 0.043 per cent. In 3 cases the thrombosis was unimportant as a cause of death and probably occurred just before the patient died. In 2 cases there was recanalization and some collateral circulation. In 1 case there was a polycythemia.

Gilman, T.: A Critical Evaluation of the Neutral Red Excretion and Acid-Secretion Tests of Gastric Function in Normal Subjects, and in Subjects with Gastric Disorders. *Gastroenterology* 1944, 3, 188.

The recent evidence concerning the wide range of acid secretion by normal subjects as well as the

fluctuations observed in the same subject on different occasions has shaken the confidence of clinicians in the value of determination of the acid secretion as a diagnostic procedure. The method is rapidly losing its popularity. In fact, Schindler and Alvarez have recently expressed opinions which may be regarded as the death knell of fractional gastric analysis as a clinical test. The present investigation confirms the opinions recorded by numerous investigators concerning the limitations of the study of acid secretion in the diagnosis of gastric disorders but provides information which promises a new lease of life to a modified form of gastric analysis in the clinic.

In this study it has been established (1) that the excretion of neutral red by the normal gastric mucosa is constant in the same subject on different occasions (2) that disturbances in dye excretion can be easily recognized and (3) that a disturbed neutral red excretion can be regarded as evidence of gastric dysfunction. For these reasons alone, this test deserves recognition as a diagnostic procedure in the clinic.

Moreover, the modified neutral-red test has other qualities which make it invaluable both in the clinic and in the laboratory. It is simple, inexpensive, time-saving, free from unpleasant reactions and above all, it is extremely sensitive.

The improved neutral-red-excretion test, when the rate of excretion and concentration as well as the intensity to which the injected neutral red can be concentrated, are recorded, has been shown to be an excellent indicator of the excretory function of the gastric mucosa.

This test has been applied to 50 individuals with apparently normal gastric function and standards of normality have been suggested.

In 15 of these normal subjects both neutral red excretion and acid secretion were examined repeatedly over a period varying from one week to six months. These repeated studies revealed that the acid secretion fluctuated considerably in the same subject while the excretion of neutral-red remained remarkably constant.

From the study of 500 cases with gastric dysfunction criteria of abnormal neutral red excretion expressed quantitatively have been tentatively suggested. A comparison of the tests for neutral red and acid secretions revealed that the neutral red test is not only reliable but is also more sensitive than the acid-secretion test as an indicator of gastric function.

Acid secretion and dye excretion do not necessarily parallel one another either in healthy or abnormal stomachs. It is suggested that acid secretion and dye excretion are indicators of two apparently independent functions of the gastric mucosa.

In view of its simplicity, reliability and sensitivity the neutral red test can be recommended as a means of obtaining valuable information concerning the functions of the gastric mucosa both in the clinic and in experimental studies.

HARRY W. FINE, M.D.

Cleland, J. B.: *The Length of the Small Intestine.*
Med. J. Australia, 1944 2 359.

The considerable variation in the length of the small intestine is the subject matter of this article. Naturally with a variation in the length of the small intestine there is also a considerable variation in the amount of area occupied by its mucosa.

One would be led to suppose that with such a difference in area there might be a concomitant effect upon the physiology of the subject. However persons with short intestines do not in any way appear to be handicapped during life. Whatever effect the difference in area of the small intestine might produce would now seem to be a matter of quite useless speculation.

In 1941 quite by chance the author who is professor of Pathology at the University of Adelaide Australia happened to notice during the course of a postmortem examination on a woman, aged fifty years that the small intestine seemed very short. As it was detached he proceeded to measure it and found that it was only 15 feet long from the termination of the duodenum to the cecum. This finding led him to make a series of measurements of the jejunum and ileum in more than 100 bodies. His observations showed that remarkable variations existed, ranging from 13 feet (in 2 cases) to 37 feet. The intestine (jejunum and ileum only) was measured after having been detached from the mesentery as close as possible to the intestine itself in such a way that the gut scissors could rapidly slit up the lumen. Probably a number of small kinks were left varying from subject to subject so that all the measurements probably are somewhat less than the actual length.

Arranged in order (inches being neglected) the length of the small intestine in 100 subjects of both sexes was 13 feet in 2 15 feet in 2 16 feet in 4 17 feet in 2 18 feet in 3 19 feet in 4 20 feet in 3 21 feet in 12 22 feet in 7 23 feet in 16 24 feet in 5 25 feet in 6 26 feet in 13 27 feet in 9 28 feet

in 5 29 feet in 2 30 feet in 1 31 feet in 1 33 feet in 1 35 feet in 1 and 37 feet in 1

The author carefully lists the results of measurements in 60 male subjects and also in 40 female subjects. The figures show that the small intestine may be quite short in both males and females. However, whereas 5 of 60 male subjects had a small intestine of 30 feet in length or more none of the 40 female subjects had a small intestine longer than 29 feet. The length did not seem to bear any definite relationship to the length or size of the subject. Even children may have a longer small intestine than some adults. In a boy aged fourteen years the small intestine measured 28 feet in length. In a girl, aged nine years the measurement was 19 feet, 6 inches and in a male infant aged nine weeks, a measurement of 16 feet 4 inches was found.

The author made a careful check-up in the cases of both the lowest and the highest measurements to ascertain what connection, if any, could be found between the diseases from which these subjects suffered and the length of the jejunum and ileum. It was impossible to determine whether disease conditions had any bearing on the length of the small intestine or vice versa.

Nature does indeed present strange incongruities. For example an examination of the bodies of two full-blooded Australian natives gave the following findings. In a woman aged twenty two years, the small intestine measured 21 feet 6 inches in a man, aged thirty five years, the length was 16 feet, 6 inches. In a female half-caste, aged thirty five years, the small intestine was 28 feet long, and in a half-caste boy aged twelve years it was 21 feet, 6 inches long.

Surprising as these variations in the length of the small intestine are it seems even more surprising to find that this difference in area seems to have no effect upon the physiology of the subject, nor upon the disease which caused the death of the subject.

MATTHEW J. SCURRY, M.D.

GYNECOLOGY

EXTERNAL GENITALIA

Quinet, A. A. Vaginal Cytology in Premature Puberty (Citologia vaginal na puberdade precoce) *An. Brasil gín.* 1944, 18 102

In newborn infants the organism is impregnated with maternal follicular hormones and the cells of the vagina are therefore estrogenic in type. They are predominantly well defined squamous polygonal cells with a transparent cytoplasm some of them with granules arranged around the nucleus which is generally pyknotic, well defined and small in comparison with the volume of cytoplasm. From the twenty first day on the type of cells changes. The cells become round or oval with large nuclei and there is an abundance of mucus and of leucocytes. Some of the cells are surrounded by a translucent halo.

The author studied the vaginal cells in 3 little girls who showed precocious puberty. They were three years and seven months, seven years and eight months and four years and two months of age, respectively and showed well developed sexual characteristics. Though they were at an age when the second type of cells described would ordinarily predominate they revealed a predominance of the estrogenic, squamous polygonal cells. A similar type of cells can be produced in girls before puberty by the administration of estrogenic hormones.

There was another peculiar characteristic in the cells of these cases. There was a dark line running through the cells in the oval ones along the long axis and in the round ones near the center of the cell. This line seemed to be caused by a condensation of the nuclear chromatin, and it was found chiefly in the most superficial cells of the stratum spinosum.

AUDREY G. MORROW M.D.

Jeffcoate T. N. A., Davis, T. B. and Harrison, G. V.: Intraepidermal Carcinoma (Bowen's Disease) of the Vulva (A Report on 2 Cases) *J. Obst. Gyn. Brit. Empire* 1944, 51 377

According to Knight, the histological criteria for the diagnosis of Bowen's disease are (a) hyperkeratosis and parakeratosis (b) acanthosis with marked thickening of the rete malpighii which appear club-shaped (c) loss of stratification of the individual cells with disorientation, (d) the presence of nuclear clumping, "corps ronds" nuclear grains and mitotic figures (e) an intact basement membrane and (f) marked vascularity of the subpapillary zone with round-cell infiltration. He points out that it is usually necessary to examine several sections before finding all these features.

The appearance of the lesion to the naked eye shows some variation, but typically it is a dull red raw area with a clearly defined circinate or serpiginous outline. The area is on the same level as the

surrounding skin or at most, is only slightly raised but there is a sharp line of demarcation between the healthy and diseased tissues. The surface is moist but may become encrusted in part the appearance of the lesion being very similar to that of Paget's disease of the nipple. It does not show any of the usual characteristics of malignancy there is no friability or fixation and metastases in lymphatic glands or elsewhere are rare. It may be confused with eczema or with tuberculous or other ulcers and Knight points out that when it occurs on the vulva it may be mistaken for kraurosis or leucoplakia. Indeed, the latter may occur with Bowen's disease.

Clinically the disease runs a slow course, often lasting many years. It sometimes heals spontaneously in the central areas while it advances at the periphery. It can at any time, however change into a frank epithelioma and this is true especially when it encroaches on mucous membranes. At such sites the change into epithelioma with rapid spread and the development of metastases are common.

On the vulva the lesion occurs at any age, before or after the menopause the ages for recorded cases vary from twenty five to seventy three years with an average of approximately fifty years. In the second case reported here, however the patient was eighty-one years old. The symptoms produced are pain and pruritus the area often being extremely tender. In long-standing cases a history of remissions and exacerbations is the rule.

Two cases of intraepidermal carcinoma (Bowen's disease) of the vulva are described in detail. In the first patient the lesion ultimately spread to the vagina and immediately changed into epithelioma which rapidly assumed the most malignant characters. The clinical features of this condition are described, and the diagnosis etiology and treatment discussed. Special reference is made to its pathology and its relation to Paget's disease of the vulva. It is suggested that cases previously described as Paget's disease have in fact been cases of Bowen's disease and it is recommended that the name "Paget's disease" be restricted to the well known lesion of the nipple. The results of treatment in these 2 cases also substantiate other reports that the use of radium is not satisfactory and that excision of the affected area is preferable. In neither of these cases was the growth process arrested by radium application.

CHARLES BARON M.D.

MISCELLANEOUS

Davis, A.: The Treatment of Amenorrhea with Combined Anterior Pituitary Follicle-Stimulating Hormone and Chorionic Gonadotropin *J. Obst. Gyn. Brit. Empire*, 1944, 51 401

The author cites experimental evidence of the value of the combination of chorionic gonadotropin

and pituitary follicle-stimulating hormone, and states that it is more potent than either of its individual constituents as a gonadal stimulant. Twenty-seven patients with amenorrhea were treated by the preparation synapoldin.

After the mechanism of menstruation was discussed the rationale of treatment of functional amenorrhea with pituitary or pituitarylike gonadotropins rather than by substitution therapy with estrogen and/or progesterone, was emphasized.

Clinical classification of amenorrhea, based on the organ presumably primarily responsible, is presented.

The dosage used was 1 cc. of synapoldin given intramuscularly three times weekly for three weeks after careful examination had been made to determine the cause of the amenorrhea. This examination included the basal metabolic rate roentgenograms of the pituitary fossa, diagnostic curettage, and hystero-graphy with lipiodol. The majority of the patients were of the primary pituitary type showing the characteristics of a mild Froehlich syndrome.

Occasionally gross enlargement of the ovary was seen as a complication. This, however gradually subsided after treatment was discontinued.

Results showed a permanent cure of 14 of the 27 cases temporary improvement in 6 and no improvement in the remainder. The duration of the previous amenorrhea did not seem to affect the result.

The author believes this preparation is the best so far offered for amenorrhea especially that of the pituitary type with a mild Froehlich syndrome. Frequent examinations are necessary to control ovarian hypertrophy. Hemorrhage is a contra-indication to continuance of the treatment.

T. FLOYD BELL, M.D.

Thomas, R. B. and Cannefax, G. R.: Sulfonamide Therapy of Gonorrhea. *J Am M Ass.*, 1944, 136: 63.

The authors report the results of their experience in the treatment of gonorrhea in 555 women (200 negro and 355 white). All were hospitalized and under constant observation during the period of treatment.

The histories were of little value in making the diagnosis since the most frequent symptoms in the patients with gonorrhea, as well as in those without infection were lower abdominal pain and vaginal discharge. Nonspecific cervicitis and vaginitis were frequently encountered. On admission, cervical and urethral cultures and smears were taken in all cases. Rectal and Bartholin smears were taken only when there was an indication of infection in these areas. Beginning five days after treatment cultures were taken every other day and if they were negative until an uninterrupted total of 6 cultures had been examined.

All patients were started on sulfathiazole with the exception of a few who were given sulfadiazine. The

TABLE I.—RESULTS OF SULFONAMIDE TREATMENT BY RACIAL GROUP

Method of treatment	White (555)				Negro (200)			
	Cure		Failure		Cure		Failure	
	No.	Per Cent	No.	Per Cent	No.	Per Cent	No.	Per Cent
1st course, 5 day	174	66	141	49	182	90	20	10
2d course, 5 day	34	27	94	73	28	23	9	7
Total cures	208	70			210	83		
Total failures			207	70			9	4

total dosage amounted to 20 gm. 1 gm. being given four times daily for five days. Some patients were given a larger amount of the drug. If five days after completion of the treatment the cultures still were positive, a second course was given. Patients who did not then become negative were considered to be sulfonamide-resistant and were given foreign-protein therapy and sulfonamides. If this failed, artificial fever therapy with a sulfonamide, or penicillin (10,000 units every three hours, for a total of 60,000 units) was used.

The results obtained paralleled those for males. Seventy-one per cent of the patients were cured by the first course of sulfonamides, and 81 per cent were cured by either one or two courses of treatment. About one-third of those who were subjected to foreign protein therapy and 23 of 25 treated by artificial fever gave negative cultures. Ninety-four per cent of the penicillin-treated sulfonamide-resistant cases were cured following the administration of a total of 60,000 units.

The disease was much easier to cure in the negro than in the white patient (Table I). In no negro was it necessary to use artificial fever and in only 1 instance was penicillin used.

In some complications of the adnexa and Bartholin's glands the sulfonamides failed to produce a cure, although clinical and symptomatic improvement was noted despite the fact that the cultures remained positive.

There were few cases of sulfonamide reaction. In 3 patients the ureters became blocked during hot weather. This was prevented subsequently by increasing the fluid intake. Three patients developed hematuria.

J. ROBERT WILLIAMS, M.D.

Greenblatt, R. B. and Street, A. R.: Penicillin for the Treatment of Chlamydia-resistant Gonorrhea in the Female. *J Am M Ass.*, 1944, 136: 61.

The sulfonamides are effective in curing a little better than 55 per cent of the cases of gonorrhea in the female. One hundred and nine patients were treated with penicillin and of these 93 per cent had had one or more courses of sulfonamides. The total dosage of penicillin varied from 60,000 to 150,000 units. No untoward reactions were encountered.

Five patients received a second course of penicillin because of relapse. The second round of penicillin varied from 120,000 to 300,000 units. These patients remained negative after the second course of therapy.

Dosage should not be reduced to the minimum necessary for good results but should be maintained at a sufficiently high level so that the development of penicillin resistant strains may be thwarted. To this end it is recommended that 150,000 units be used.

T FLOYD BELL, M.D.

Phaneuf, L. E.: The Changes in Operative Gynecology during the Last Quarter-Century. *J. Am. Med. Ass.*, 1944, 136: 139.

The last quarter of a century has shown much progress in surgical technique with emphasis on careful dissection and ligation of individual vessels with fine material rather than mass ligation of the tissues. The treatment of carcinoma of the uterine cervix has changed from surgery to irradiation. However, a few gynecologists have again turned to surgery in well selected cases. Improvement in technique, and the use of blood transfusions and of the sulfonamides has lowered the mortality from the Wertheim operation.

The treatment of carcinoma of the uterine corpus and fundus still remains surgical with ablation of the adnexa, with or without preoperative radium and postoperative high voltage x ray therapy. Improvement here has also come through early diagnosis by means of curettage for women who bleed irregularly at or after the menopause.

Improvement in the operation of myomectomy has resulted in more conservative surgery of fibroids. In young women who are still in the childbearing age, the advantage of myomectomy rests in the fact that the functions of menstruation and reproduction are not abolished.

Supravaginal hysterectomy still remains the type of operation most often performed. However an increasing number of gynecologists have turned to panhysterectomy as a prophylactic means against carcinoma of the cervical stump. The author almost entirely performs the total operation. If radium or x rays are used for fibroids a thorough curettage of

the uterus should be done to rule out malignant disease. In the young whose ovaries should be conserved and in the good surgical risks surgery is still accepted as the better method of treatment.

During the last two decades vaginal hysterectomy has been reborn and its performance in all gynecological services is now commonplace. Since it plays such an important role in gynecology it is not likely to be again abandoned.

Originally vesicovaginal fistulas were the result of the trauma of childbirth. With the increase of pelvic operations the so-called surgical fistulas now greatly outnumber the obstetric. The latter offer greater difficulty in closure. Two helpful adjuncts to the operation are the Schuchardt incision, and suprapubic cystostomy. Metal wire still has a place in the repair of vesicovaginal fistulas.

The current and useful method of cauterization of the cervix has resulted in the less frequent performance of trachelorrhaphy and amputation of the cervix.

A significant advance has been made in the surgical treatment of uterine prolapse, cystocele and rectocele because of a better understanding of the structures that hold the pelvic viscera in their normal position. The supportive structures are exposed by layer dissection rather than by superficial dissection of the surface mucous membrane of the vagina. Better operative results have been secured. Uterine suspension and fixation have definitely decreased in frequency.

The treatment of pelvic inflammatory disease is more conservative. The sulfonamides are decreasing the incidence of this condition. Puerperal sepsis still heads the list of causes of maternal deaths in this country. Here again prophylactic measures are beneficial and the sulfonamide drugs are valuable.

Progress with ovarian tumors has been due to better classification and the recognition of certain of the rare ovarian new growths. There are no great differences of opinion as to the operative management of ovarian tumors. True neoplasms of the ovary should be removed surgically because of the danger of malignant degeneration. This should be done when the diagnosis has been established.

T FLOYD BELL, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Herman L., and Greene L. B.: Pregnancy after Bilateral Ureteral Transplantation; Report of a Case after Bilateral Ureterocutaneous Transplantation. *J Urol* Balt., 94, 52-300.

Very few pregnancies after ureteral transplantation have been reported, as might be anticipated from the comparative rarity of this operation and, what is equally important, the disinclination of women with serious physical defects to get married. Congenital malformations of the female genitalia which preclude either impregnation or successful gestation rarely occur in association with exstrophy or other maldevelopment of the bladder and contribute little to sterility in the type of case under discussion. Randall and Hardwick in 1934 found in the literature up to 1934 reports of 28 children born to 20 mothers with exstrophy of the bladder. Not all of the mothers had had ureterointestinal anastomoses. The literature since 1934 contains only 1 case report.

The deliveries in 21 of the 28 cases collected by Randall and Hardwick were normal and without unusual incident. It would seem that cesarean section is rarely necessary in women who have submitted to

ureterointestinal anastomosis for exstrophy of the bladder.

Females with acquired urinary lesions requiring ureteral transplantations are often beyond the child-bearing period or incapable of gestation because of the seriousness of the disease. The opportunity, therefore for pregnancy following this operation are rare. The authors describe the case of a fully matured Polish girl aged nineteen years, who had had a tumor (probably a meningocoele) removed from the base of her spine at the age of six months. Her first admission to the urological department of the Pennsylvania Hospital was on July 19, 1939. She had never experienced the desire to void and had had constant dripping of the urine from the urethra, except on a few occasions when lying quietly on her right side or walking carefully also there had been rectal incontinence when the bowel movements were liquid.

After numerous methods of treatment had been tried unsuccessfully cutaneous ureterostomy was carried out. Several months after this she married and soon became pregnant. On February 9, 1944 at about the eighth month of pregnancy she went into labor and was quickly delivered of a dead hydrocephalic infant. This obviated the necessity for cesarean section which had been anticipated as a means of preventing rectal and other possible injuries. Bilateral retrograde pyelograms made shortly before delivery illustrated the very satisfactory condition of the renal pelvis which had escaped dilatation, including that incident to pregnancy. The kidneys were normal in function and only mildly infected.

DANIEL G. MORROW, M.D.

Finn, W. F.: Thrombocytopenic Purpura in Pregnancy. *Am. J. Obst.* 94, 48-497.

Purpura hemorrhagica is at best a rare disease, but its coexistence with pregnancy is rarer still. The author gives in detail the classification, symptoms, diagnosis and treatment of the disease. Three cases are reported in detail. The patient usually comes to the doctor complaining of bleeding from the mouth, epistaxis, or hematuria. The acute phase is more common in early life and the patient may progress to death from anemia or intracranial hemorrhage. The most striking physical sign is the presence of purpuric spots varying in size from the point of a pin to the head of a pin. Infection of the mouth at Vincent's organisms is a common association.

The treatment of thrombocytopenic purpura is both medical and surgical. In the acute phase, the patient is placed in bed, a high protein and high vitamin antianemic diet is given, and fœcol is administered. Blood, citrated and fresh, or red-cell transfusions are given to control the bleeding, to keep the red-cell count above 2,000,000, and to keep the blood pressure above 90. Within the past year

Fig. Retrograde pyelogram at eighth month of pregnancy. Note normality of pelvic outflow. Head of fetus is enlarged as result of hydrocephalus.

intrus pectin in dosage of from 3 to 9 gm. a day has been recommended by Isaacs. This checks the bleeding without affecting the platelet count. Either spontaneously or because of this therapy the acute phase will subside. In this interval foci of infection are removed or splenectomy is done. Splenectomy is contraindicated if there is any doubt of the diagnosis, if there is a history of recent drug ingestion, and above all, if sternal puncture fails to reveal megakaryocytes in the bone marrow.

How is the child affected by the thrombocytopenic purpura of the mother? Mosher states that 50 per cent of the infants die in utero or after delivery. Burnett and Klass, at the other extreme, believe that if the fetus develops purpura, it is not essential thrombocytopenic purpura but symptomatic purpura or it is due to a familial platelet defect. Rushmore, in 1925 reported 7 instances in which purpura was present in both mother and child. The author adds 3 more examples of this: the first baby dying of congenital thrombocytopenic purpura and the second living (also an example of congenital thrombocytopenic purpura). EDWARD L. CORNELL, M.D.

James, H. W. Jr and Neill, W. Jr: The Treatment of Carcinoma of the Cervix during Pregnancy. *Am. J. Obst.*, 1944 48 447

In formulating a plan for a clinical situation as rare as the association of pregnancy and carcinoma of the cervix, one must draw upon the collective experience of the literature as well as upon one's own cases.

The authors believe that a general rule for the handling of these cases must take into account the obstetric and social background as expressed in the desire of the prospective parents for the child, as well as the extent of the disease. If there are other children, or if the parents do not care to assume the ever present risk of an abnormal child, they see no reason to advise any course except interruption of the pregnancy and adequate irradiation therapy.

The risk of an abnormal fetus cannot be statistically stated at the present time with certainty but it seems probable that its upper limit is 20 per cent. If the parents and physician for any reason wish to assume this risk, it is justifiable to proceed with irradiation during pregnancy with a view to obtaining a living child at term. If the pregnancy is at the fifth month or beyond the risk of an abnormal child is substantially less. The mother's prognosis is intimately related to the clinical extent of the disease. The general experience has been that most cases are discovered early and the prognosis has been parallel but somewhat poorer than for corresponding but uncomplicated groups.

If treatment during pregnancy with a view to obtaining a normal living child at term is decided upon certain points in technique may be stressed. It is important that no high voltage roentgen ray therapy be employed because of the obvious dangers of substantial depth dosage in the region of the developing child. The authors omit the use of tubes within the

cervical canal. This is done for the twofold purpose of securing all possible distance from the baby and also to guard against the onset of labor by dilatation of the cervix. The entire treatment is carried out with tubes held in a cloth plaque against the cervix. The authors have preferred to use a large amount of radium for a correspondingly short period of time. In the 11 cases reported the dose varied from 1 614 mc. hr to 3 925 mc.

The prognosis of carcinoma diagnosed at term and treated by cesarean section plus panhysterectomy or irradiation is grave. This is in a large measure due to failure of the attending physician to suspect the diagnosis and apply such simple clinical methods as speculum examination and biopsy even in the presence of vaginal bleeding during pregnancy.

EDWARD L. CORNELL, M.D.

LABOR AND ITS COMPLICATIONS

Mackie, M. A.: Comparison between Surgical Induction of Labor by Means of the Rectal Tube and Surgical Induction of Labor by Artificial Rupture of the Membranes. *Statistical Survey Med. J. Australia* 1944, 2 458.

In an endeavor to discover the more efficient method of surgical induction of labor the author carried out a statistical survey of the results obtained by rectal tube induction and by artificial rupture of the membranes. Pregnancy had advanced to at least twenty-eight weeks in every case considered and all cases in which either method was attempted have been included. During this period there were 278 cases of tubal induction and 393 cases of artificial rupture of the membranes.

Toxemia was the indication for induction in 88 per cent of the cases in which a rectal tube was used and in 82 per cent of those in which induction was accomplished by artificial rupture of the membranes. Seven maternal deaths (a mortality rate of 2.5 per cent) followed tubal induction while only 2 deaths (a mortality rate of 0.5 per cent) followed induction by artificial rupture of the membranes. Five of the deaths which followed tubal induction were due to infection and the 2 others were due to obstetric shock after normal deliveries. The 2 deaths which followed artificial rupture of the membranes were due directly to the primary disease. The condition became morbid during the puerperium in 17.2 per cent of the patients in whom labor was induced by rectal tube, compared with this finding in but 13.5 per cent of those in whom labor was induced by artificial rupture of the membranes.

In this series the total fetal mortality rate for tubal induction was 37.2 per cent while the total fetal mortality rate for artificial rupture of the membranes was 19.2 per cent.

When the cases are divided into two groups—(1) those with less than thirty-four weeks of gestation and (2) those with thirty-four weeks of gestation or more—it is shown that in group 1 the fetal mortality rate was 70 per cent following tubal induction and

72 per cent following artificial rupture of the membranes and in group 2 it was 23.4 per cent following tubal induction and 14.1 per cent following artificial rupture of the membranes.

The time from artificial rupture of the membranes to delivery was less than that from tubal induction to delivery in all groups. The average time from induction to delivery after the insertion of a rectal tube was forty two hours while that from artificial rupture of the membranes to delivery was twenty hours.

With regard to tubal induction, 5 inductions were unsuccessful, 1 patient being delivered by lower segment cesarean section and 4 requiring subsequent artificial rupture of the membranes to induce labor. In 1 case prolapse of the umbilical cord occurred.

Artificial rupture of the membranes was unsuccessful in 3 cases and both patients were delivered by lower-segment cesarean section. Prolapse of the umbilical cord occurred 3 times.

This statistical survey indicates that the results of artificial rupture of the membranes are immeasurably superior to those of tubal induction.

DANIEL G. MCCARTHY, M.D.

NEWBORN

Hennessey, J. P.: True Knots of the Umbilical Cord. *Am. J. Obst.*, 944, 48, 518.

True knots of the umbilical cord are not infrequent and are occasionally of a complicated nature. They are usually harmless, since they are rarely pulled tightly enough in utero to obliterate completely the lumen of the vessels, or to cause the death of the fetus. They usually result from the active movement of the child.

Fig. 1. True knots of the umbilical cord.

According to von Winckel, two conditions are necessary for their formation: a cord which in length exceeds twice the distance from the umbilicus to the vertex, and a small fetus or a large quantity of liquor amnii, which ensures mobility of the former. No doubt in many cases the knot remains open until labor begins when the tension imparted to the cord by the descent of the fetus closes it. When the knot has been tightened during pregnancy distortion of the cord will persist even after it has been untied because of the effect of the continued pressure on Wharton's jelly but if it has formed only during delivery it can easily be straightened out. Although it is possible for the knot to become so tightly drawn as to cause a partial or complete obstruction of the cord circulation, this occurs very rarely.

Seven original cases are described, and a tabulation of 32 cases from the literature, supplementing the table published by Browne, is given. There were 2 antenatal deaths of the fetuses. In each case there was one true knot drawn tightly. In 2 other cases there were 2 true knots in the cord.

EDWARD L. CORNELL, M.D.

Anderson, N. A., and Nelson, W. E.: Clinical Observations in the Treatment of Epidemic Diarrhea of the Newborn. *J. Pediatr.*, 5, 1944, 25, 3, 9.

A review of the literature on epidemic diarrhea of the newborn revealed an average fatality of 43 per cent. In this article the therapy of 28 cases of epidemic diarrhea is discussed.

In the early neonatal period the frequency and character of the stools is so variable that the diagnosis of epidemic diarrhea is often difficult. Unexplained diarrhea in any infant or diarrhea in 3 or more infants calls for isolation.

Twenty-eight of 76 term infants and 4 of 9 premature infants who were exposed developed the disease within a period of seven days. Twenty-eight of the 32 infected infants were treated. Seven were considered critically, 8 seriously, 8 moderately and 5 mildly ill. One death occurred in a seventeen-day-old premature infant.

Stool cultures revealed only one organism of any possible significance. This was a para-aerogen type of paracolon bacillus. Loss of weight was characteristic, most marked in the severe cases, and often preceded other clinical manifestations of the disease. Other clinical characteristics were general toxic diarrhea, and in the severe cases a low carbon-dioxide-combining power of the blood.

Treatment of these infants consisted of oral administration of a mixture of glucose and Ringer's solution, parenteral administration of additional fluids, correction of acidosis by the parenteral administration of alkali, oral administration of ascorbic acid and thiamine chloride, blood and plasma infusions as indicated, and, in addition, the administration of succinylsulfathiazole (1 gr. every four hours).

Acidosis was corrected by the administration of a 5 per cent solution of sodium bicarbonate or by the

intravenous and/or subcutaneous administration of 11/6 sodium-lactate solution in calculated amounts. Clinical improvement was noted during or shortly after the administration of alkali. Oral feedings were gradually restored to normal as the infants improved.

In discussing the benefits of this therapy the authors pointed out the fact that control cases were impossible. However the parenteral use of fluids was considered essential. The rapid improvement in acidotic infants after the administration of parenteral alkali impressed the authors in respect to this type of therapy. Succinylsulfathiazole had no noticeable effect on the disease.

MISCELLANEOUS

Lentz, J. W., Ingraham, N. R., Jr., Beerman H., and Stokes, J. L.: Penicillin in the Prevention and Treatment of Congenital Syphilis. *J. Am. M. Ass.*, 1944, 126: 408.

Twelve pregnant women with early symptomatic syphilis and 2 with early latent syphilis, none of whom had previously received any type of anti-syphilitic treatment, were given intramuscular injections of sodium penicillin at four hour intervals in doses of from 25,000 to 50,000 units dissolved in 1 cc. of sterile saline solution, the course continuing for a period of approximately eight days until a total dosage of from 1,200,000 to 2,500,000 Oxford units had been given. In 9 infants with early congenital syphilis neither they nor their mothers having received other anti-syphilitics the same technique of treatment was used for the same period of time, with the difference that the individual doses were so regulated that in 4 cases the total injections ranged between 16,000 and 19,000 units, and the remaining 3 dosages were 2,935, 10,631 and 11,111

units per pound of body weight, respectively. Two of the 9 children died prior to completion of the treatment, these deaths however were not ascribed to the penicillin.

All 14 pregnancies are included in this report merely to show that the higher dosages are well tolerated by the pregnant women and that apparently the highest amount (2,400,000 Oxford units) should be used when the physical condition is satisfactory. Seven of the 14 women (6 with early initially symptomatic syphilis, and 1 with early latent syphilis) have so far delivered and these cases are reported in some detail. None of these 7 women started penicillin prior to the mid-term period of their pregnancies, and none had attained seronegativity at term yet all the infants seemed healthy. 4 were seronegative at birth and 3 became negative in less than a month postpartum and have remained so for short periods of observation. Roentgenograms of the long bones of 4 of the infants were taken both at birth and at the age of six weeks or later in each instance they were normal.

Three of the infants with early congenital syphilis have been followed up long enough to make a report possible (ninety-nine, ninety-seven and seventy-nine days, respectively after administration of the sodium penicillin). All 3 infants had relatively high blood serologic titers initially but these dropped sharply to normal in 1 and to relatively low levels in the 2 others (3½ unit and 8 units respectively), all became clinically normal to physical examination. The 2 infants who showed definite roentgenographic changes of syphilitic osteochondritis and periostitis have resumed approximately normal bone development.

In conclusion the authors urge caution in initiation of the penicillin treatment because of the Herxheimer reaction just as in other anti-syphilitic medication.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Colby F. H.: Renal Complications of Reiter's Disease. *J. Urol.*, Balt., 1944, 51: 415.

The author's review of 3 cases gives the essential features of the syndrome known as Reiter's disease. All 3 cases occurred in young males. The typical triad of urethritis, conjunctivitis and arthritis was present. There was insufficient evidence to show that the disease was contracted by sexual exposure. Bacteriology has failed to identify the causative agent. The course of the disease is unaffected by any known therapy including penicillin. Instances of permanent joint disability are rare although a few are reported. Recurrent eye, joint, and urinary symptoms may occur and severe renal complications may be encountered. JOHN A. LOFF, M.D.

BLADDER, URETHRA, AND PENIS

Donaldson, S. W., and Ratliff, R. K.: Extravesical Lesions Causing Bladder Neck Obstruction. *Radiology* 1944, 43: 319.

The authors comment upon the lack of reports of bladder neck obstruction due to extravesical causes. During the past two years there have been 5 cases of this type treated by the authors. Three women had complete urinary retention due to fibroids of the uterus associated with uterine ptosis in 2 cases. Recovery was complete in these cases following hysterectomy. One male who had a sacral chordoma which caused vesical neck obstruction was given a permanent suprapubic cystostomy and a male who had a sarcoma of the pelvis which caused acute retention of the urine died in the hospital.

It is believed that extravesical lesions causing obstruction at the bladder neck should offer little difficulty in diagnosis. They should be suspected if the cystoscopic examination is negative in the presence of a pelvic mass which persists after the bladder is emptied. The extravesical tumors usually do not cause the rectal symptoms and venous stasis which accompany most retroperitoneal tumors, and for that reason the diagnosis of such lesions may be arrived at by the process of elimination. Careful pelvic and rectal examinations together with cystograms usually establish the diagnosis.

Osteomyelitis with soft-tissue abscess has been observed to cause bladder distortion but never obstruction. Fractures of the pelvis cause obstruction by contusion or rupture rather than by pressure. Lesions of the lower bowel involving the rectum, even though far advanced, rarely cause vesical neck obstruction. This is probably due to the mobility of the gut and to the pelvic fascia, which serves as an effective barrier.

Treatment in cases of bladder-neck obstruction should be instituted in order to relieve the obstruc-

tion and to restore the urinary organs to as near normal function as possible. Early treatment is indicated in order that kidney damage may not become so severe that it cannot be remedied. The blood urea and renal function should be determined.

Cystograms of excellent diagnostic value are reproduced in the original article.

GENITAL ORGANS

Frame, E. G., and Jewett, H. J.: The Excretion of 17 Ketosteroids in Carcinoma of the Prostate: Personal Experiences. *J. Urol.* Balt., 1944, 53: 339.

The total excretion of urinary 17-ketosteroids has been determined in 16 cases of carcinoma of the prostate and compared with that of 8 controls in a similar age group. Five of the patients with carcinoma had been castrated from ten to twenty-four months previously. In all cases the total 17-ketosteroids were separated into alpha and beta fractions since the literature contains suggestions that such separations may be of clinical importance.

The results indicate that the total 17 ketosteroid excretion in older men is less than in men between the ages of twenty and forty but the amount in cases of carcinoma of the prostate does not differ from that in control cases of a similar age group. There also is no significant difference in the relative amounts of alpha and beta fractions present in the patients with and without carcinoma of the prostate. The patients with carcinoma of the prostate who had been castrated from ten to twenty-four months previously and in whom there had been a recrudescence of the disease, showed no difference in 17 ketosteroid excretion from that in the untreated cases. JOHN A. LOFF, M.D.

Donahue, C. D.: The Use of Stilbestrol in Carcinoma of the Prostate. *Northwest M.* 1944, 43: 284.

At present the use of stilbestrol is rather empiric. Yet there is a fairly sound basis that justifies its employment. The interrelationship of the pituitary, thyroid, adrenal, prostate, and testicular glands is common knowledge. If there is an imbalance created in this interrelationship tissue growth is thrown out of balance.

Orchiectomy has definitely proved its value in malignant growths of the prostate, yet there are instances in which no improvement was noted. This is in part explained by Herbert's autopsy reports, in which he cited enlargement of the adrenal glands to four and seven times the normal size. This occurred in 1 patient who failed to respond to castration. Undoubtedly the pituitary gland was playing an important part in androgen control. It is the

author's belief that variability in response to the castration method may be explained by the close interrelationship between the endocrine functions.

He does not think that stilbestrol has been given a fair trial by some, especially when he reads that 1-mgm. doses by mouth have been given with unsatisfactory results.

More than 40 cases are under treatment at the present time. In consideration of the dosage the author has become more bold and followed the course of others in administering 40 intragluteal injections 3 mgm. each a total of 200 mgm. and then a maintenance dose of 1 mgm. each night on retiring. Patients are required to call at irregular intervals for recheck and repeat with a second course if necessary.

The largest total dosage was 1,440 mgm. given over a three and-one half year period. There has been no unfavorable reaction.

As far as maintenance dosage is concerned the author is not certain that 1 mgm. doses are sufficient.

As to toxic effects only 1 case seemed to be definitely reacting to stilbestrol with nausea and vomiting, which prompted the discontinuance of the treatment. Other side-effects were minor namely swollen breasts and sore nipples.

JOHN A. LOFF, M.D.

Marshall, V. F. Subtotal Perineal Prostatectomy: Presentation of a New Technique. *J. U. A. Balt.* 1944, 52: 250.

The perineal approach for prostatectomy is an established urological procedure.

Four advantages of subtotal perineal prostatectomy i.e. the removal of almost all or all of the capsule but with retention of most of the bladder neck, over perineal intracapsular enucleation seem noteworthy.

1. An unrecognized carcinoma may be removed.
2. Many fibrotic infected or stone-bearing prostates are best treated by this procedure.
3. Hemorrhage is well controlled under vision.
4. Subsequent urinary control compares favorably with that following other methods.

The approach for subtotal perineal prostatectomy follows Young's classical description and need not be described here. Occasionally Belt's modification is used but the exposure is not quite so good.

After the rectal surface of the prostate is exposed, biopsies are taken from any suspicious areas and frozen sections made. If carcinoma is present Young's radical operation is done. The fascia overlying the seminal vesicles and ampullae is incised transversally and the lower portions of these organs are well exposed. These lower portions may now be divided distal to right angle clamps (so-called gall bladder clamps) and the stumps transfixed with 0 chromic catgut, but it is usually easier to do this later. When desired the vesicles and ampullae may be dissected free and removed *in toto*. Then the tissues on the sides of the prostate are pushed upward by blunt dissection with the handle of the scalpel so that all loose tissue is crowded into the

region of the anterior commissure. An incision is next made two-thirds of the way around the lower circumference of the urethra at the junction of the apex of the prostate and membranous urethra care being taken to avoid the external sphincter region. When necessary a cystoscope can now be passed for examination of the bladder. One blade of a heavy curved scissors is inserted into the urethra and placed in the groove between the upper part of the lateral lobe and the anterior commissure. The other blade is in a corresponding position outside of the whole thickness of prostate superiorly and in the space previously created by blunt dissection. An incision is now made back to the muscle of the bladder neck and the step repeated on the other side. By palpation the more or less vertical groove on either side between the lateral lobes and the bladder on the interior of the bladder outlet is found and with the scissors the upper halves of the lateral lobes are excised from the bladder. A few bleeding vessels are usually found on the cut surface of the bladder muscle and these are clamped and ligated with 00 plain catgut. Prostatic lobe forceps are applied to the lateral lobes, occasionally only one at a time to allow more room. The lobes are pulled downward and rotated laterally, the prostatic urethra being spread open to give a clear view into the bladder and of the remaining sites to be divided. The incision between the lateral lobes and the bladder is continued downward almost to the trigone, any bleeding vessels being ligated in course. The whole prostate is turned sharply downward and traction applied this provides a complete view of the trigone. If the middle lobe is up under the trigone, an incision with the scalpel is made across the apex of the trigone and down to the prostatic tissue, the middle lobe is enucleated from its connections with the bladder and the flap of the trigone raised bluntly which exposes the vesicles ampullae, and chief vascular supply of the prostate these are clamped cut, and ligated to remove the prostate. If the gland has not enlarged under the trigone this is usually not necessary and right angle clamps can be applied and the gland removed. The clamped tissue is transfixed with sutures of 0 chromic catgut.

The closure is proceeded with in the following fashion.

Chromic 0 catgut is used for suture material. A mattress suture is placed in the roof of the bladder neck and the roof of the urethra and tied, the strip of mucosa on the anterior commissure being ignored. This approximates the top of the new outlet. A similar suture is placed through the apex of the trigone, including the bladder neck musculature beneath it and into the floor of the urethral stump. This approximates the floor of the new outlet and leaves the excess opening into the bladder on either side. A 30-cc. Foley bag catheter (usually size 22 or 24 French) is inserted through the urethra into the bladder and inflated. The bladder is thoroughly irrigated before complete closure. The openings on either side are now closed transversally with in-

interrupted single sutures through all the layers of the bladder wall. At a suitable point on either side, one of these sutures also passes through the lateral wall of the urethra. Considerable care is taken that the sutures are tied only tightly enough to approximate the tissues so that there will be no necrosis. The closure should be watertight to moderate irrigation and, if not, a few extra sutures may be placed at the required points. The wound is irrigated, and if appreciable infection is expected about 1 gm. of sulfonamide powder is dusted in it. One thin rubber tissue drain is inserted to the suture line. The levator muscles are loosely approximated with interrupted single catgut sutures; the subcutaneous tissue with "o" plain catgut, and the skin with fine silk. The drain is brought out one angle of the wound and sutured to the skin with silk.

MISCELLANEOUS

Haller, C. G. and Myers, G. B.: The Male Climacteric; Its Symptomatology, Diagnosis, and Treatment. *J. Am. Med. Ass.* 944, 126-172.

The authors point out the subjective similarity of the male climacteric, psychoneurosis and psychogenic impotence. Because of this fact it is undertaken to distinguish these conditions by laboratory tests and to determine if the male climacteric is a normal accompaniment of the aging process or a pathological condition. Further, the therapeutic value of hormones is investigated.

Since it is known that in the female the menopause is accompanied by an elevation of the gonadotropin titer an investigation was undertaken to show whether or not such elevation is a true index of testicular failure.

Twenty-five normal men in the age group from the third to the tenth decade were subjected to the gonadotropic content of twelve hour night urine. The ovarian weights of the injected white rats averaged 12.3 mgm., which finding was similar to that in the injected control rats.

In the cases of 12 castrated men the ovarian weight was increased fivefold (58 mgm.) which is to be interpreted as testicular failure. The urinary gonadotropic elevation was further revealed in 8 prepubertal castrates. Again the gonadotropin increase was revealed in 20 cases by hyalinization of the seminiferous tubules and clumping of the Leydig cells.

Urinary gonadotropic assays in 38 men complaining of symptoms similar to the female menopause demonstrated two distinct categories: (1) 15 patients with normal gonadotropic assays, and (2) 23 individuals in which the hormone was decidedly elevated, which suggested a lack of testicular function and this was confirmed by histological examination of biopsy specimens in 8 individuals.

Testosterone propionate was exhibited in 20 of these patients, 9 of group 1 and 10 of group 2. The 20 patients in the last group were subjectively im-

proved in one week, and 17 were completely relieved at the end of three weeks but the remaining 3 continued to have psychic and constitutional symptoms in spite of therapy for several months after which vasomotor and urinary symptoms were abolished. In 2 cases the loss of sexual vigor was refractory to therapy until 50 mgm. of testosterone propionate was given five times weekly. In 14 cases the therapy was withheld and all symptoms including sexual impotency returned, and this was again reversed by the exhibition of testosterone propionate. None of the patients demonstrated improvement when placebos were substituted for the hormone without the patient's knowledge. The subjective improvement, followed by return to the original symptoms, failure of the placebos to afford subjective relief, and, finally improvement with re-establishment of therapy are demonstrated by the concomitant curve of urinary gonadotropic assays.

In reviewing the symptomatology the authors noted similar symptoms in the groups except that in the former group there were distinct hot flashes while in the latter the symptoms were present more or less, throughout life with the onset following psychic trauma.

It was concluded that the male climacteric may occur as early as the third decade (1 case reported was that of a twenty-five-year-old man) but it is a relatively rare syndrome, probably affecting only a small proportion of men who live into old age, and therefore, distinctly a pathological process.

Androgen therapy is contraindicated in (1) the presence of carcinoma any place in the body (2) the presence of edema since androgen tends to produce sodium and thus water retention and (3) the presence of normal testes, since testosterone inhibits spermatogenesis and disuse atrophy of the Leydig cells.

The authors advise a therapeutic test for the male climacteric in instances in which laboratory facilities are not available. Testosterone propionate (35 mgm.) is given intramuscularly five days weekly for two weeks. If there is no subjective improvement or a return of sexual potency two conclusions are permissible: (1) that the patient does not have the male climacteric, or (2) that excessive dosage of testosterone is necessary which makes the therapy impractical. On the other hand, if the patient responds it is then essential to determine if he is suffering from testicular inadequacy and this is accomplished by discontinuation of the therapy with a return of symptoms symptomatic continuation with placebos and finally further androgen treatment with relief of the symptoms again.

It was the finding of the authors that complete testicular failure can be usually controlled with 25 mgm. of testosterone propionate given thrice weekly in some cases given once weekly and rarely with 10 mgm. given once or twice weekly. Implantation of pellets is advocated in instances in which two or more intramuscular injections of testosterone propionate are necessary weekly. From 4 to 8 pellets

are implanted subcutaneously in the thighs and provide control for periods of from six to ten months. Methyl testosterone has been found to be disappointing as a means of replacement therapy and moreover it is toxic in large doses.

ROBERT LICH, JR. M.D.

Trattner H. R., and Walzak, B. J.: Studies Concerning Effects of Calcium on the Urinary Tract. *J Urol* Balt. 1944, 52: 357.

Effects following the intravenous injection of 10 cc. of a 10 per cent solution of calcium gluconate on the musculature of the renal pelvis and calyces, ureter and bladder were studied by four different methods in a total of 282 patients.

The injected calcium did not alter spastic states which included spasm of the renal pelvis and calyces in 17 per cent, of the ureter in from 17 to 71 per cent, and of the bladder in 30 per cent of the patients. There was persistence of pain in 30 per cent of the patients having ureteral colic. No notations of urinary pH were recorded.

Excluding instances of slight to moderate relaxation, the injected calcium was found to produce a marked relaxation which overcame a previously existing spastic state in 30 per cent of the renal pelvis and calyces, in 27 per cent of the ureters and in 57 per cent of the bladders. Forty per cent of the patients having ureteral colic experienced complete relief from pain. No notations of urinary pH were recorded.

When relaxation followed calcium injection defects which had appeared in the urogram because of contracted or spastic states disappeared. This finding proved to be of important assistance in urographic interpretation. It was also observed that a greater amount of opaque solution could be tolerated by a patient with minimal or complete absence of pain.

From bladder filling determinations before and after calcium injection it was found that the urinary pH has an important and very definite relation to calcium action in that relaxation of the bladder occurred in a greater degree with and greater frequency on the acid side particularly between pH 5.0 and 6.3 while diminution in capacity of the bladder i.e. increased tone or spasm, took place to a greater extent and with more frequency on the alkaline side. Thus there appears to be an optimal acidity of the urine in which the antispasmodic or relaxing effect of the calcium is more likely to take place.

The injection of calcium for the purpose of relaxation is contraindicated when the urine is alkaline because of decreased effectiveness, negative results or reversal of action. There is less certainty of relaxation when the urine is of high acidity than when it is within the optimal acid range.

The incidence of relaxation should be expected to occur in a greater percentage of cases than is reported in this article if calcium is injected when the urine is in the optimal acid range indicated, or if the patients are properly acidified prior to such administration.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Helfet A. J.: Acute Manifestations of Yaws of the Bones and Joints. *J Bone Surg* 1944, 26 672.

In the tropics yaws is the most common bone and joint disease. It is very often associated with tropical ulcers and cracked, painful skin especially on the feet. The manifestations of yaws are so similar to syphilis that differentiation often becomes very difficult. It is said that yaws does not affect the viscera and the central nervous system. The symptoms of syphilis are characterized by bone pain especially at night and when the limb is warm and dependent. This is associated with the picture of bone sclerosis. Patients affected with yaws present a more rapid and painful picture.

The history is rarely older than a few weeks and already definite, characteristic features are seen on the roentgenogram. There are single or multiple "punched out" areas, subperiosteal necrosis of bone with raising of the periosteum and deposition of new bone which often takes the shape of onion-layer.

Yaws near joints may simulate arthritis, as it causes pain, swelling, muscle spasm, and limitation of motion. Syphilitic gummatous lesions rarely show these clinical manifestations. Yaws in the shaft of long bones frequently resembles septic osteomyelitis. The disease is found in any part of the skeleton. The tibia, lower end of the femur, medial end of the clavicle and lower end of the humerus are predominantly involved. The Wassermann and Kahn reactions are always positive.

The microscopic picture of yaws is very similar to that in syphilitic lesions with the exception that endarteritis obliterans—which is so characteristic in syphilis—is absent in yaws. The joints and tendon sheaths are very often affected by this disease. In joints yaws produces a painless chronic synovitis. Articular cartilage is not affected. When the tendons are affected the formation of ganglia or tenosynovitis is very common.

Arsenicals are used in antiyaws treatment. The author used acetylsalicylic acid or novarsenobillon (N.A.B.) or alternate doses of bismuth and sulfostab. Under this treatment subjective complaints disappear readily. The objective findings, however, subside very slowly.

The author states that his investigations on yaws in Africans in Africa were hampered by two facts. The African has little appreciation of time, and therefore, the past and present history was unreliable. Also he is very often affected by a multiplicity of diseases which obscure the clinical picture considerably. The most common diseases were chronic malaria, dysentery (entamoeba histolytica) and bilharziasis.

GEORGE I. REISS, M.D.

Boyd H. B.: Congenital Talonavicular Synostosis. *J Bone Surg* 1944, 6 682.

The author reports 4 additional cases of talonavicular synostosis, a condition previously described as being unusual and very rare.

A white girl of ten years, a white boy of ten years, the boy's father aged forty five, and the boy's grandmother aged seventy-two—all presented talonavicular synostosis. They had very little or no complaints.

The author points out that the relationships of the last 3 patients suggest a hereditary nature of the condition.

A number of x ray reproductions show the fusion of the talus and the navicular bone very distinctly.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

King, B. H.: Lantzon's Periosteocapsuloplasty for Congenital Dorsal Subluxation or Congenital Overlap of the Fifth Toe. *South. M. J.* 1944, 37 614.

Simple amputation of the fifth toe for congenital overlap or subluxation has not eradicated the pressure symptoms about the plantarolateral aspect of the fifth metatarsal head which recur postoperatively. A new technique is herewith reported. Eighteen such fifth toes have been corrected by an operation called periosteocapsuloplasty (Lantzon's) in 11 soldiers with satisfactory results. All of the patients complained that the involved fifth toe rubbed on their shoes and uniformly exhibited dorsal clavi.

The operative procedure is described in detail and is accompanied by two diagrams, one of which is herewith reproduced.

Periosteocapsuloplasty

Fig. 1. a, top, Diagrams lateral view of fifth toe and metatarsal before operation. b Diagrams lateral view of correction obtained by operation.

After the fifth metatarsophalangeal joint is exposed, the extensor digitorum longus tendon is cut from its distal insertion and transplanted onto the fifth metatarsal neck. The dorsal periosteocapsulopostotal layer covering the fifth metatarsophalangeal joint is reflected mediolaterally. This in addition to the tendon transplantation, augments release of the "bow string" with complete reduction of the existing subluxation deformity. A mattress suture of the reflected capsulopostotal layer introduced under the metatarsophalangeal joint not only reverses the "bow string" but maintains it. When this suture is tied no intervening tissue remains between the bony structures and the skin. The redundant capsular element is now transfixed under the fifth metatarsophalangeal joint. The skin is closed in the usual manner. Copious dressing and adhesive are the only immobilization used. The author recommends weightbearing three weeks postoperatively.

SAMUEL L. GOVERNALL, M.D.

FRACTURES AND DISLOCATIONS

Allende, G., and Freytes, M: Old Dislocation of the Elbow. *J Bone Surg.*, 1944, 26 691

During the past ten years the authors have treated 35 patients with old dislocations of the elbow who presented themselves for consultation from twenty days to five months after their injuries. If a dislocation is not reduced immediately osseous and fibrous changes occur around and in the elbow joint which make manual reduction impossible.

Fractures were associated with the dislocation in 13 of the cases in this series. Fracture of the medial epicondyle in 8 cases, of the tip of the coronoid process in 3 cases, of the lateral epicondyle in 1 case, and of the lateral condyle in 1 case. Fracture of the head of the radius has never been found in old dislocations.

Ossification of the posterior and anterior aspect of the inferior extremity of the humerus scar formation in the olecranon fossa, and shortening of the triceps were the outstanding pathological changes observed in these elbow joints.

Operative reduction of the dislocations was performed in all cases. The patient was placed face down on the table, and an incision was made on the posterior aspect of the elbow joint. The shape and size of the incision varied. The ulnar nerve was located, freed and retracted. The triceps was severed following an inverted U line. The ends were retracted proximally and distally and to both sides until the radius became visible laterally and the humerus became visible medially. The joint was opened by flexing the arm. Fibrous tissue and ossification were removed. The ends of the triceps muscle were sutured with catgut or No. 34 stainless steel wire. The ulnar nerve was replaced. The skin was sutured. A plaster-of-Paris cast was applied from the axilla to the metacarpophalangeal joints the elbow being kept at an angle of 130 degrees in the cases with stable reduction and at an angle of 90

degrees in cases in which a tendency toward redislocation was noted.

In from eight to ten days after the operation the cast was opened. Exercises and hot salt baths were given and the arm was replaced into the cast after each treatment. This was done for a period of one month.

Functional results are described as being satisfactory. The elbow was painless and stable with a range of movement that varied between 40 and 120 degrees in the various patients discussed.

Other methods of treatment of old dislocation of the elbow were discussed. Farabeuf recommended in dislocations less than four or five months old, the use of strong traction by flexing and extending the arm and then pronating and supinating it with the object of breaking down adhesions and facilitating later manipulative reduction. Watson Jones recommended in some cases the use of Thomas's sham reduction which consists in flexing the elbow at a right angle and keeping it so in a sling for three weeks after which the patient forms a nearthrosis by active movement. Arthroplasty was very successful in the hands of Putti and Serra.

The authors finally discuss the indications for 3 surgical approaches: the posterolateral approach of Kocher, the transelecranal approach in which vital hum screws are used to approximate the separated fragments and the transtendinous approach.

GEORGE I. KRIS, M.D.

Ponassi I: Causes of Failure in the Treatment of Congenital Dislocation of the Hip. *J Bone Surg* 1944, 26 775

A study has been made of 120 patients with congenital dislocation of the hip with the object of determining the causes of failure in the treatment of this condition.

The cases were divided into the following three groups:

Prenatal dislocations in which the dislocation is present at birth.

Postnatal dislocations in which the patient presents a predislocation at birth which slowly pro-

Fig. 1. Abduction bar applied.

Fig. 2. a, left, Outward rotation of the foot is locked at 75 degrees. b, There is free inward rotation.

Fig. 3. With the abduction splint applied, the femoral heads are centrally situated in the acetabulum.

gresses during the first year of life until it becomes a well established dislocation when the patient begins to walk. The 'bifidation' of the acetabular roof shown on the roentgenogram is characteristic of most of these cases.

Doubtful cases in which both the primary and secondary acetabula are well developed but in which the roentgenogram shows them to be separated by a bony ridge. In these cases it was impossible to determine how and when the dislocation took place.

Treatment in the prenatal cases generally resulted in failure. Putti's abduction splint is indicated only during the predislocation stage of the postnatal dislocations.

The anteversion of the femoral neck plays an important role in the maldevelopment of the hip after immobilization.

Except for the prenatal dislocations and a few dubious and postnatal cases which could not be reduced, the greatest number of failures in the treatment of congenital dislocation of the hip is to be found

1. In epiphysitis of the femoral head

2. When there is a tendency of the head to become subluxated, which occurs at the beginning of the walking exercises

3. In osteoclerosis of the acetabular roof

If better results are to be obtained in the treatment of congenital dislocated hips we shall have to direct our efforts to diminishing the incidence of epiphysitis and to establishing a careful and prolonged after treatment to favor the development of the acetabular roof. It was noted how frequently cystic atrophy of the femoral epiphysis occurs, and that a flattened head results in 50 per cent of these cases. The cystic atrophy starts to develop from the fifth to the seventh month of immobilization, and progresses until the removal of the cast. The longer the immobilization, the greater and more frequent is the cystic atrophy. As has been mentioned, the author believes this lesion to be related to the poor biological condition of the primary acetabulum, where the femoral head is placed after reduction. The best conditions for the head will be provided by an early development of the new hip joint with all its components but mainly the development of the

synovial lining. In a baby a good part of the femoral head is cartilaginous and we know how much the nutrition of the cartilage depends upon the synovial fluid.

It seems logical that a joint, which is the main organ of motion will develop better with motion than with rest. The retention of the head in the primary acetabulum should be the principal aim of treatment during the first months after reduction. As soon as the danger of redislocation has disappeared, the rebuilding of the new hip joint will be better accomplished by the establishment of controlled motion.

From the study of this series it has been learned that the persistence of the Trendelenburg sign for more than two or three months after the patient has begun to walk indicates a poor prognosis. If the gait does not recover and a positive Trendelenburg sign persists the femoral head is subluxated on each step because of the tilting of the pelvis, and the reconstruction of a good acetabular roof becomes impossible.

It has been said by different authors, and mainly by Krida and Badgley in this country that one of the main causes of dislocation is the anteversion of the femoral head. Because of this anteversion it is necessary that the leg be maintained in inward rotation to obtain centralization of the femoral head in the acetabulum and outward rotation should be avoided for a long period after treatment. The best way to accomplish this would be to strengthen the inward rotators of the hip which have been weakened during the period of immobilization.

The authors believe the postreduction treatment of the congenitally dislocated hip should be directed as follows

1. Functional treatment should be started as early as possible to avoid or diminish epiphysitis of the reduced hip.

2. Prolonged controlled, functional treatment with the legs in abduction, should be carried out in order to secure the central position of the femoral head in the acetabulum, and to make possible a good development of the acetabular roof. Outward rotation of the legs should be avoided, but free inward rotation should be allowed in order to stimulate the development of the inward rotators.

One year ago the authors began to treat a group of congenitally dislocated hips in the following way:

1. The reduction of the hip is done following Reddon's technique—the method which has been used in the State University of Iowa Hospitals for many years.

2. A well molded, bilateral plaster hip spica is applied with the hip in 90 degrees of flexion and from 60 to 70 degrees of abduction in both unilateral and bilateral dislocations. This position is recommended by Waldenstrom in order to avoid overstrain on the adductors which "press the femoral head with great force against the acetabulum and the anterior part of the capsule. If the reduction is stable the knee joints can be left free. If the head redislocates easily the plaster cast must be extended below the knees. This position is maintained for from three to four months and then under anesthesia the legs are brought to Lange's position with as much inward rotation as possible. A bilateral long leg hip spica is applied for two additional months.

3. Following the five or six months of immobilization, the controlled functional treatment is begun. With the object of (a) keeping the legs in abduction, (b) avoiding the outward rotation of the legs and (c) giving them free motion in other directions an abduction bar was devised. This splint consists of an iron bar with a plate inserted on each end. The plates which are attached to the heels of the baby's shoes, have free inward rotation, while the outward rotation is locked at 75 degrees. The distance between these two plates can be controlled by sliding the two pieces which form the bar. The legs should form an angle of 100 to 120 degrees.

This abduction bar is kept on the patient continuously except for the daily bath, from two to six months following removal of the cast. At the end of two to six months according to the development of the hip joint the child is allowed to walk for two hours daily for the next month. The splint remains applied for the rest of the day. The length of time the patient can walk each day can be determined from successive roentgenograms but probably during the first year after reduction daily walking should not exceed from two to six hours. The splint must be applied at night for at least three years following reduction, even if the roentgenogram shows a well developed hip. We are dealing with a congenital deformity which has a strong tendency to persist.

The author's observations on open reduction and shelf operations are as follows:

Open operation proved to be useful in several of the older cases in which an hour glass constriction of the capsule, a too-long round ligament, or adhesions of the capsule to the wall of the iliac bone were the causes of the irreducibility. The hour glass constrictions and the adhesions of the capsule were late sequelae of old congenital dislocations. In no patient under four years of age were such conditions found and consequently the author concludes that open operation is rarely indicated in young children.

The shelf operation was successful only in the cases in which the femoral head could be well placed in the center of the acetabulum. The shelf with the head above the primary acetabulum gave a poor functional result.

ROBERT P. MONTGOMERY, M.D.

Savini, C.: Ambulatory Treatment of Fractures of the Lower Extremities. *Am J Surg* 1944, 66: 44.

In the ambulatory treatment of fractures of the lower extremities after the fracture has been reduced and the limb immobilized the patient should be allowed to leave the bed as soon as possible. Getting out of bed is the first and most important part of the treatment. Walking is of secondary importance, and should be left for a later time and mostly to the discretion of the patient.

To be out of bed insures better nutrition, better digestion, a better general condition and, as a consequence, better healing of the fracture.

Patients should not be urged to walk too soon. Generally they are too eager to walk. However once they have acquired confidence, without any instruction, encouragement or assistance they generally move around and walk within a very short time.

An ambulatory treatment is seldom possible when the fracture was treated with open reduction.

Fig. 1. Models of stirrups. A, for fracture of leg; B for fracture of hip joint. Each stirrup is made with duraluminum $\frac{1}{4}$ inch wide and $\frac{1}{8}$ inch thick. Two plates of pliable metal are attached to the top branches of the stirrup serving to hold the stirrup on the ring of the bandage covering the leg. The bases of the stirrups touching the ground are covered with rubber.

Fig. 2. Apparatus for fracture of hip complete eight 5 pounds. Plaster of Paris bandage was removed from the leg to permit massage (Courtesy of American Journal of Surgery.)

but it was very successful when fractures were treated manually and required only a light plaster of Paris bandage to keep the fragments in place.

From January 1 1933 to December 31 1943, 148 of a total of 232 cases of fractures of the lower limbs referred to the author's care were treated ambulatorily: 10 fractures of the neck of femur, 5 fractures of the patella, 23 fractures of the tibia and fibula, 20 fractures of the tibia, 16 fractures of the fibula, 49 fractures of the malleoli, and 25 fractures of bones of the foot.

All these patients were treated as emergency cases, and the fracture reduced immediately or as soon as possible after their admission to the hospital. A plaster-of-Paris bandage and a metal stirrup were applied at the same time. Patients with fracture of the leg were generally out of bed the next day after admission, some of them a few days later and on the average were discharged from the hospital in one month.

In the treatment of fractures of the leg and foot, after reduction the fractured leg is immobilized and at the level of the tuberosity of the tibia, a length of plaster-of-Paris bandage is applied sideways and rolled around the leg to form a 1 inch wide and 1 inch thick ring as a part of the plaster-of-Paris covering the leg, to serve as a good support to the metal stirrup. The stirrup is longer than the leg so that when the patient is standing, it rests on the

floor the foot remaining suspended and not touching the floor. Thus walking is made easy and there is no danger of traumatic flat foot.

For fractures of the hip joint, the treatment is as follows:

Following reduction and after a light bandage of plaster-of-Paris has been applied on the whole limb, another stirrup is used: the external branch of which is made long enough to measure the distance from a little below the crest of the iliac bone to the floor and its internal branch to reach the middle part of the thigh of the patient. To support the stirrup, the plaster-of-Paris bandage covering the entire limb is reinforced with two rings, one just below the crest of the iliac bone, circling the lower part of the abdomen and the other at the middle part of the thigh. When the stirrup is applied its base rests on the floor and the foot remains suspended.

The stirrups can be made of duraluminum; they are then smaller and lighter in weight; they are kept fixed to the limb with plaster-of-Paris bandages, day and night.

Only a few plaster-of-Paris bandages should be used in order that the resulting cast be very light and thin. To insure immobilization, we must trust more to the stirrup than to the thickness of the bandage.

A complete apparatus with stirrup for immobilization should not weigh more than 5 pounds for a fracture of the femur and not more than 3 pounds for a leg fracture. ROBERT P. MORREHEAD, M.D.

Bernstein, A., and Stone, J. R.: March Fracture. A Report of 307 Cases and a New Method of Treatment. *J Bone Surg* 1944, 26: 744.

From this series of 307 cases of march fracture the following conclusions were drawn:

Prior to the introduction of "speed hikes" and prolonged marches in the curriculum of basic training, march fractures were rare entities. Soon after this change in the curriculum occurred, this syndrome was seen.

This pathological condition occurred in soldiers irrespective of age, height, weight, and general body build.

No usual or unusual deformities of the foot are associated with this condition.

One or more of the metatarsals may be involved at the same time, or at different times during the same training cycle.

There is no relation between preduction occupation and the development of a march fracture.

Contrary to general opinion, this condition occurs in the colored soldier although not nearly so frequently as in the white soldier.

The treatment, as described in this article, was found to be adequate enough to keep the soldier on duty without missing the greater portion of his training. After six or eight weeks, the soldier is able to perform his duties as well as the man who never had a march fracture.

The method of treatment described saves innumerable hospital and training days.

In the authors' opinion the treatment of a march fracture of the foot by immobilization in a plaster of Paris bandage, as described in the literature is not indicated since this is not a complete fracture and there is no loss of position or alignment. Furthermore rigid immobilization causes bone and muscle atrophy of the involved foot and leg. When the plaster cast has been removed it is necessary for the patient to receive physical therapy over a period of several weeks before he can return to his normal duties. With the new method of treatment all this is obviated.

The treatment is not original but has been used previously for fractures of the toes, bursitis between the heads of the metatarsals and various other conditions of the foot.

Patients with a march fracture complain of pain during the push-off phase of the gait, that is when the weight is born on the heads of the first, second, and fifth metatarsals with the toes dorsiflexed and the heel off the ground. If during the gait the foot is held rigid thus eliminating motion at the metatarsophalangeal joints the pain is markedly decreased. In order to accomplish this same rigidity a steel bar from $\frac{1}{2}$ to $\frac{3}{4}$ of an inch wide $\frac{3}{8}$ inch thick and 6 inches long is countersunk into the sole of the shoe. Originally this bar was countersunk on the weight bearing surface of the sole but as the sole wore down the metal became more prominent acted as a rocker and caused discomfort. At present the steel bar is countersunk on the underside or non weight bearing surface of the sole and is held in position by 4 rivets.

The relief obtained by this means is very definite and becomes more noticeable after several days, that is as soon as the patient becomes accustomed to walking with a stiff soled shoe. In this way the patient may continue the greater part of his basic training with very little handicap. Most patients continue with their full training and are rarely hospitalized.

Occasionally the patient is further relieved by placing a felt pad along the longitudinal arch in order to redistribute the weight. The steel bar is kept in position for approximately four or five weeks at which time the fracture has solidly healed. The metal bar can then be removed and used again.

Patients with march fracture of one foot are not hospitalized but as soon as diagnosis is made clinically or roentgenographically they are sent to the Camp Shoe Repair Shop, with a requisition for a "march bar." Patients wait for their shoes to be repaired and then report back to their companies for further training. In this way hospital days and training days are saved.

The sooner the bar is applied the sooner can complete recovery be expected. Eleven cases or 3.6 per cent, did not respond to this type of treatment. The latter patients were given thirty-day sick furloughs with instructions to continue weight bearing on the

Fig. 1. Showing bar in place on nonweight bearing surface of the sole of the shoe.

injured foot as much as pain would allow. On return from furlough these patients are usually fit for full duty.

Howard J. E., Parsons, W., Eisenberg, H., Stein, K. E., and Reldt, V.: Studies on Fracture Convalescence. Nitrogen Metabolism after Fracture and Skeletal Operations in Healthy Males. *Bull. Johns Hopkins Hosp.* 944, 75, 156.

A study of the metabolism and internal environment of patients who had suffered traumatic skeletal fractures was undertaken with the hope that light might be thrown on the factors which provoke the high incidence of urinary lithiasis and the more rare renal complications with a closer understanding of the metabolic processes during fracture recovery and that therapeutic measures favoring optimal internal and external environment for the recovery of such patients might also be disclosed.

The present report deals with observations on the nitrogen metabolism of 6 patients following fractures of the large bones of the lower extremity and includes comparative studies on 3 patients after operative procedures on the femur and 1 herniorrhaphy. The fracture studies were made on males otherwise healthy whose fractures healed satisfactorily. All patients were at bed rest in casts throughout the entire period of observation. Balance studies were begun as soon as the patients' general condition permitted accurate collections of urine and feces which varied from one to seven days after the trauma had been sustained. In the osteotomy cases it was possible to collect metabolic data preoperatively as well as to make observations immediately after the operation. The results showed that all of the fracture cases showed losses of body protein of considerable magnitude. In 6 patients the average loss of body nitrogen following fracture was more than 220 gm. Expressed in terms of protein, this would be about 1,400 gm. or in terms of normal muscle protoplasm, 15 lb (7 kilos).

The authors have divided their data into two phases: the first of protein loss, the second of protein repletion. On their basis the duration of the phase of nitrogen loss in their patients averaged thirty-five and six tenths days, and the study of their data in the repletion phase shows that these patients re

plenished their lost nitrogen at a very slow rate. Nitrogen losses of a magnitude sustained by their fracture patients are probably of considerable importance to the body economy and must not be overlooked in designing therapeutic measures. The factors which might play a role in these nitrogen losses are disuse anesthesia sulfonamide compound fever and infection they are briefly discussed. Vigorous healthy male patients suffering skeletal fracture treated by ordinary methods sustain large losses of body nitrogen during the early phase of their convalescence. The catabolic nitrogen which is excreted in the urine does not reach its maximum until six days after the injury is sustained and nitrogen equilibrium is not re-established for approximately thirty five days.

Nonfracture operative cases sustain comparatively much smaller and shorter nitrogen losses and repletion is more rapid and vigorous. Disuse atrophy bed rest, anesthesia fever and infection do not account for the major part of the nitrogen losses under discussion. Sulfonamide compounds did not appear to influence the over-all nitrogen metabolism in this group of patients.

ORTHOPEDICS IN GENERAL

Ghormley R. K. and Hinchey J. J.: The Use of Aluminum Acetate in the Treatment of Malacic Diseases of Bone. *J Bone Surg* 1944, 26 8

The results obtained by the authors in treatment of malacic diseases of bone with aluminum acetate were as follows:

Of 10 patients suffering from osteoporosis who had followed the treatment six months or more 8 were improved subjectively and 2 were the same as before treatment. All of 8 patients who had Paget's disease and who had followed the program for six months or more were improved symptomatically. In 4 patients who had osteitis fibrosa the condition had improved in 3 and 1 of these had followed the treatment for only two months. The improvement in 2 cases was considerable as demonstrated by

roentgenograms. In the case of 1 patient who had had osteogenesis imperfecta with repeated fractures and deformities since 1914 and who was unable to work and could hardly get around the condition was improved after six months of treatment so that he could get around on crutches and work at a desk. He reported that he felt much better.

The clinical improvement both subjective and objective seems striking enough to the authors to warrant a further trial of the treatment.

The preparation of aluminum acetate used was as follows:

Rx	Solution of aluminum acetate	13v
	Syrup of tolu balsam	15ml
	Honey	to make 32ri

Directions: 1 teaspoonful, three times a day

For children the dose was reduced according to the age and size of the patient.

The use of milk was recommended in all instances, if milk could not be tolerated by the patient, calcium in some other form was used. Vitamin D was administered in all cases.

Ward R.: The Epidemiology of Poliomyelitis. *J Bone Surg* 1944 26 879.

Perhaps the best way to begin a discussion of the epidemiology of poliomyelitis is to state that we do not yet know how poliomyelitis is transmitted.

Studies on the natural history of human poliomyelitis provide no support for the belief in the olfactory portal of entry of the virus, but they suggest that the entire alimentary tract may provide a site or sites of primary attack and invasion. The skin remains a possible portal of entry. The chief mode of elimination of virus at present appears to be by way of the stools. While the striking seasonal incidence the evidence for the human alimentary tract as a portal of entry and the finding of abundant virus in stools sewage and flies, do not establish these latter materials as definite links in the infection chain nevertheless they suggest that poliomyelitis should be placed tentatively in the group of excremental infective diseases until other modes of spread become established.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Lange, K., and Boyd, L. J.: Use of the Fluorescein Method in the Establishment of the Diagnosis and Prognosis of Peripheral Vascular Diseases. *Arch. Int. M.* 1944 74 175

Injected intravenously fluorescein can be made visible by a beam of long wave ultraviolet radiation on reaching any area of exposed skin or mucous membranes. A photoelectric method to indicate the arrival of the dye and to measure the intensity of staining may also be used.

In over 1000 patients examined by this method the only untoward reaction was vomiting of short duration during the injection this occurred in 11 patients. Experiments on animals showed extremely low toxicity. The dye diffuses immediately through the capillaries into the interstitial spaces and is partly adsorbed to the plasma proteins. Pathological changes of which do not change the amount of fluorescein immediately available for diffusion. Dead cells do not stain. It has been shown by ultrafiltration experiments that the amount of dye diffusing into the tissue depends on the intracapillary pressure. Changes in capillary permeability alter the amount which diffuses as well as the concentration. Even slight inflammation increases the fluorescence of the tissue. Pigmentation especially in colored people, makes the test unreliable. Determinations of the normal circulation time between the arm and the lip is between fifteen and seventeen and a half seconds, while the time to the legs should not exceed twice this figure.

In 9 patients with acute embolism of the legs it was possible to define exactly the lowest possible level of amputation as far as the skin was concerned, and to decide at once on the probable formation of sufficient collateral circulation to avoid amputation. Block of the sympathetic lumbar ganglions should be performed to avoid mistakes caused by vasospasm. The immediate diagnosis of thrombotic occlusion can also be made. Small gangrenous areas in arteriosclerotic peripheral vascular disease can be judged as to the prospect for healing, localization or further spread varicose ulcers of the leg can be judged as to their outlook for healing and skin grafting, and syphilitic leg ulcers have a specific picture distinguishing them from varicose ulcers. Thromboangiitis obliterans has usually a higher fluorescence than one would expect from the lack of arterial pulsations. Vasospastic disorders have a low fluorescence during the attack, which immediately returns to normal or even increases above normal on blockade of the sympathetic chain. Rubor due to inflammation in a limb with arteriosclerotic peripheral vascular disease can be well differentiated from venous congestion. Thrombophlebitis of the superficial vessels can be well made out as long as it is in

flammatory and the extent of the inflammation can be outlined. WALTER H. NADLER, M.D.

Lazarus, J. A., and Marks, M. S.: Aneurysm of the Renal Artery—True and False—with Special Reference to Preoperative Diagnosis. *J. Urol.*, Balt. 1944, 52: 199.

Aneurysm of the renal artery is a rare clinical entity as evidenced by the fact that the authors were able to collect only 75 cases from the literature. This includes the case here presented.

A history of trauma was elicited in 34.7 per cent of these cases. Among the other etiological factors associated with this condition are systemic debilitating infections and atherosclerosis.

Pathologically aneurysms may be classified as (a) true, and (b) false. True aneurysm is a sacular dilatation of an artery containing all the elements of the arterial wall and results from weakening of the arterial wall as a result of sclerosis, fatty degeneration involving the elastic fibers from some debilitating systemic infection, or from atherosclerosis. A false aneurysm is a sacular dilatation of an artery due to trauma which results in complete disruption of the continuity of the arterial wall either in part or in its entirety in which the limiting walls from without inward consist of adventitia, laminated blood clot and endothelium.

Small aneurysms of the renal artery usually give rise to no symptoms. Larger aneurysms however, usually give rise to symptoms, the most common of which is pain in the loin (62.7 per cent). A mass was felt in the loin in 30 per cent of the recorded cases.

The presence of an opaque ring shadow with a dense periphery on the x-ray film in the region of the renal pelvis is an extremely valuable diagnostic sign of this disease.

The indicated procedure in the treatment of aneurysm of the renal artery is immediate nephrectomy with ligation of the renal artery proximal to the point of origin of the aneurysm.

JOHN J. MALONEY, M.D.

Monahan, D. T.: Ligation of the Aorta and Both Common Iliac Arteries for Aneurysm. *Surgery* 1944, 16: 519.

A forty nine year-old syphilitic negro was laparotomized for aortic aneurysm. The tumor was found to extend from above the inferior mesenteric artery to and involving the bifurcation into the common iliac arteries so that all three of these arteries involved by the aneurysmal sac.

Immediately proximal to the aneurysmal mass, a rubber band about 3/4 inch wide was placed under the aorta and sutured in the shape of a funnel with three No. 1 interrupted silk mattress sutures so placed that if the knots were to slip the sharp stitches would rub on the rubber and not on the aorta itself.

This band interrupted about three-fourths of the circulation into the aneurysm.

Three weeks later the abdomen was again opened. The aneurysm was about the same size and pulsating, although not as strongly as before the partial occlusion. A curved clamp was inserted under the aorta just proximal to the aneurysm and a piece of rubber band $\frac{1}{8}$ inch wide was brought under it below the first band and sutured with 3 fine silk sutures so that the vessel was completely occluded. There was no palpation then of either the aneurysm or the common iliac vessels.

Again somewhat more than a month later the abdomen was opened the area of the second rubber band was exposed, a curved clamp was placed behind the aorta at this site, and 2 heavy silk ties were placed but not tied. At this point brisk bleeding was encountered, the source of which was a tear in the inferior mesenteric artery about $1\frac{1}{2}$ inches from its point of entry into the aneurysm. This vessel was clamped and tied as were also both common iliac arteries about 1 inch from the aneurysm. The heavy silk ties proximal to the aneurysm were then tied. The patient had a relatively uneventful recovery and convalescence. For three months after the last operation the patient complained of pains in the right leg and foot but he was always able to be up and about. These pains were obviously due to the fact that the right leg was not so well supplied with collaterals as the left. Sudden death then occurred from bleeding into the third portion of the duodenum from a perforation of the aorta immediately above the area of occlusion.

Autopsy disclosed that the area of occlusion of the aorta had been transformed into a cicatricial band of cartilaginous consistency and the aneurysm itself and the arterial branches leading away from it had shrunken and filled with old organized clot. The epigastric vessels were competent but not dilated. There were many small vessels which could be seen coursing over the pelvic peritoneum. There was no evidence of a diminished blood supply to the sigmoid colon. Immediately above the occluded area of the aorta there had developed a small secondary aneurysm, with perforation into the duodenum. Syphilitic aortitis was demonstrated microscopically.

The 7 successful (in Bigger's sense) occlusion operations for aortic aneurysm, all reported since 1930, are also briefly discussed. The author arrives at the conclusion that in the region of the lower abdominal aorta at least an occlusion in stages is distinctly feasible and that it would seem likely that from the standpoint of circulatory efficiency many older patients also could withstand total occlusion in stages.

JOSE W. BARROGAN M.D.

Castillo, G. R.: A Contribution to the Forms of Arteritis (Contribución al estudio de algunas arteritis). *Boh. Hosp. Caracas*, 1944 43 53

This is a monograph on the general subject of arteritis wherein the writer quotes, frequently at some length, from current articles and texts by such

authors as Buerger, Edgar V. Allen of the Mayo Clinic, Samuel Silbert and his collaborators, Loz, Magidday, Galloway and Finlay on diabetic gangrene, the lecturers at the 1936 meeting of the Société Internationale de Chirurgie (Vol. II) E. Forgue in the *Precis de Pathologie Externe* for 1939 (Tome I) and numerous Spanish authors as well as Deas, Lewis and Raynaud whose experience and study in this field have led to the acceptance of their expressions of opinion and their published data as medical axioms.

Of course the author does not accede unequivocally to every pronouncement of every authority. Thus, he does not subscribe on the basis of his own material to the pronouncements of Buerger with regard to the etiological influence of race in thromboangiitis obliterans and he is unable to find evidence in Venezuela of any etiological factor in (some) diseases of the foot. Also he does not seem enthusiastic about the newer forms of testing for the circulatory supply of the extremities, such as oscilometry and the Babinsky Heitz modification (immersion of the extremity in hot water for ten minutes), the test of Aldrich and MacClure, the histamine-injection test, the test of Moskowlitz with the Esouard bandage, the test of Cosacresco (scratching the skin with a sharp point with failure in circulatory efficiency of the reddening of healthy tissues), the test of ischemia on elevation and other postural tests, and the test of Collens and Walsky (asking the patient about with observance of the time of appearance of symptoms of claudication) and even roentgenography and arteriography. He seems to prefer simple thermometry with perhaps its combined procedures (Cohn's anesthesia rapida, the test of Brown with typhoid vaccine, and Morton and Scott's infiltration of the posterior tibial nerve), both for diagnosis and evaluation of treatment and for determining the level of any eventual amputation. No etiological effects of cold or of humidity are found in Venezuela where extremes in these conditions do not occur.

The climate about Caracas was also investigated with regard to the temperature of the skin. It was found that with a temperature of 23 C. and a humidity of 75 per cent, the average temperature of the skin on the plantar surface of the big toe was 28.9°C. and that of the dorsum of the foot 29.9°C., but with each increase in temperature of 5°C. 1°C. must be added to each of the figures given.

All of the 15 patients in the author's material were treated, time permitting, with hypertonic saline solution and if gangrene appeared and amputation could wait, preliminary ligation of the femoral artery was carried out. When amputation was decided upon, and its level determined on the basis of all available data, an attempt was made to carry out a leisurely technique with preservation of the usefulness of the limb by the formation of a proper stump. For this purpose refrigeration anesthesia as introduced and developed by Frederick M. Allen was used. Finally any antisyphilitic or other specific

treatment, and the injections of 5 per cent hypertonic saline solution were continued after the operation with a view to procuring a healthier stump and more rapid healing. Of course postoperative infection was avoided if possible with careful asepsis sulfonamides and primary closure. One of the arteriosclerotic patients (a female) was successfully treated with injections of folliculin and 2 of the patients with Buerger's disease underwent lumbar sympathectomies.

There was only 1 fatality and that occurred in the patient with the unknown type of infection (this type of case nearly always terminates fatally) who came under treatment in a condition of extreme gravity with the process evolving with great rapidity.

Four of the 6 persons with the arteriosclerotic form of ischemia had amputations and 2 recovered perfectly without operation the success being ascribed in greater part to the efficacy of the injections of hypertonic saline solution. Of the patients with Buerger's disease, 1 was a chance finding at autopsy and had never had any symptoms leading to the recognition of the condition. 2 patients who underwent lumbar sympathectomy and 3 who did not recovered perfectly under persistent injections of hypertonic saline solution and finally the 2 patients with syphilis got well one following treatment with arsenic and bismuth, and the other following the loss of the anterior half of his foot, under specific treatment combined with injections of hypertonic saline solution.

The problem of arteritis has not yet reached a solution many questions remain to be answered from the viewpoints of etiopathogenesis anatomopathology symptomatology and treatment. However students of this subject are continually bringing to light new knowledge for the benefit of these unfortunate patients who suffer so much and who are so full of hope.

JOHN W. BRENNAN, M.D.

Reynolds, J. T. and Jirka, F. J.: Embolic Occlusion of Major Arteries. *Surgery* 1944, 16: 485

Twenty-four patients were diagnosed as having an ischemia due to embolic occlusion in 27 limbs. Of these limbs 9 were not operated upon. In one patient the embolus had moved and in a second it could not be found. Thus there were 16 limbs from which an embolus was removed at operation (13 patients).

Ten of these emboli were removed within eight hours of their occurrence and all of the patients had a satisfactory return of the circulation. Of the remaining 6 emboli 4 were successfully treated (1 after twenty-seven hours) 1 result was doubtful and 1 was a failure.

Twelve of the patients died. All of these had had emboli removed. Seven died within the first few days after the removal of the embolus apparently from cardiac failure, but all had had successful restoration of the peripheral circulation. Death in 4 of the remaining 5 was not related to the heart disease or the embolus and might therefore have

been avoided. However part of the mortality rate in this series is ascribed to the fact that the authors in consonance with the teachings of de Takata, do not favor operation on an ischemic limb when there is no significant prolongation of the venous filling time and the patient can freely use the muscles of the area in which the blood supply has been threatened. As this is usually true in the presence of emboli involving the arteries of the upper extremities and the popliteal artery referral of such cases was not encouraged. In fact in all of the patients with popliteal emboli included in the present series there was evidence of adequate collateral circulation from the start none was subjected to embolectomy and those who later required amputation were those who did not receive proper care (anticoagulants intermittent venous compression and antispasmodics).

The etiological significance of physical exhaustion and changes or disturbances in the heart rate, particularly sudden variations in the intensity of digitalis therapy, is recognized as well as the importance of locating the site of the occlusion with the aid of oscillometric readings when the diagnosis is made. As soon as the diagnosis is established however heparin (5 to 10 cc.) is administered intravenously at once and the patient is rushed to operation. Heparin is also administered for as long as fifteen days after operation in doses sufficient to maintain the clotting time at about fifteen minutes, and in like manner to patients who are not treated operatively. Fifty milligrams of heparin every four hours have been found adequate to keep this level although larger quantities may often be required. (The antagonistic action of digitalis to the heparin may require adjustment of the heparin dosage.) Recently dicumarol has been used to supplement and supplant heparin. Its dosage has been as follows: 300 mgm. the first day, 200 mgm. the second day and 100 mgm. on the succeeding days.

Preoperative sympathetic nerve block and spinal anesthesia for the operation have been abandoned for fear that the relaxed artery may permit the blocking mass to slip farther to the periphery. This also applies in the case of papaverine and other vascular antispasmodics. Although sympathetic block has reportedly given considerable relief of pain the risk of loss of the embolus makes the preoperative administration of narcotics a wise method of securing analgesia. However sympathetic nerve block may be done just before the patient leaves the table and should be repeated daily during the postoperative period. Papaverine is also given postoperatively. Antispasmodics are of course indicated in cases in which operation is not done.

During this postoperative period intermittent venous compression is also used continuously, either by means of the machine specially designed for this purpose, or with a blood pressure cuff which should be inflated to a reading of between 50 and 70 mm. of mercury and that pressure maintained long enough to fill the cutaneous veins and then left off long enough to allow emptying of the vessels. All

Fig. 1. Illustration to emphasize the maneuver used to extract a clot from an artery in which the clot has become wedged into the bifurcation and in which the arteriotomy has been done below the level of the clot. Note that the end of the probe must be above the clot before it is turned and pulled down. Note also that the probe must be turned away from the direction of the major proximal branch.

though the use of refrigeration has been reserved for those extremities which are unquestionably beyond therapy its recent effect on 3 patients has been so encouraging that in the future it may well be extended. The postoperative treatment may be discontinued after a week or ten days when it is apparent that the peripheral pulse has been restored otherwise cessation of the treatment should be gradual. The sympathetic block may be dispensed with after a week. Intermittent venous compression may then be given less intensively. The anticoagulant should be continued the longest. Two or three weeks should be a minimum time.

With regard to the operation itself, although the technique seems to be practically identical with that for the various arterial ligations it is hoped that refinements in the method of extracting the clot may be made in the embolectomies most often required (those in the femoral iliac, and aortic bifurcations). This is nearly always possible by incising the common femoral artery below the inguinal ligament (Fig. 1)

JOHN W. BENDORF, M.D.

McGrath, E. J., and Hermann, L. G.: The Influence of Estrogens on the Peripheral Vasomotor Mechanism. *Ann. Surg.* 1944, 30 607

Raynaud noticed in 1862 that menstruation had no effect on patients with vasospastic attacks but that the attacks of local syncope disappeared completely with pregnancy.

The authors have made an evaluation of the effect of estrogens on experimentally produced peripheral

gangrene in the tail of the albino rat. (The mode of action of estrogens is essentially that of local liberation of acetylcholine.) All unprotected animals developed gangrene of the tail. All protected male rats also developed gangrene of the tail. Only 1 female rat, however of 40 protected with theelin developed gangrene of the tail, and in these the amount of the gangrene was incomparably less than that in the control animals.

The authors report their experience during the past ten years in translating the foregoing experimental studies into clinical therapeutics. They treated 345 patients with di-ovocyclin (Ciba) (from 0.5 to 1.0 mgrm. 3 times weekly for eight weeks). With the larger doses caution must be used in women. The authors report a high percentage of satisfactory results in the treatment of Raynaud's syndrome, thromboangitis obliterans, arteriosclerosis obliterans, acute arterial occlusion, and chronic, long-standing phlebitis. JOSEPH GASTON, M.D.

Scarborough H.: The Effect of Surgical Operation upon Capillary Resistance. *Edinburgh M J* 944, 5 335

The structure, functions, and physiological behavior of the capillaries in man are not easy to investigate. However the capillary resistance, or fragility (the ease or difficulty with which the capillary will rupture when a pressure is applied to them, can be measured with a satisfactory degree of accuracy provided that certain standard conditions are observed. The capillary walls may be subjected to a pressure strain by an increase of pressure within them, or alternatively by a negative pressure (suction) directed through the skin. Upon the latter procedure has been based a method for the accurate determination of capillary resistance. The resistance of the capillary walls to suction is assessed in terms of the least amount of negative pressure (suction) measured in millimeters of mercury that is required to rupture a single capillary in the area under examination. The procedure does not necessarily measure capillary permeability there are at present no experimental data on the relationship of any between capillary resistance and capillary permeability. Moreover the procedure does not necessarily give any information about the resistance of the capillary walls in organs and tissues within the body.

It has previously been recorded that the extravascular suffusion of blood into the body tissues or alimentary tract is immediately followed by a marked but temporary rise in capillary resistance. The increase frequently amounts to over 100 per cent. It is evident within twelve hours after the injection of as little as 4 ml. of blood into a muscle, or the experimental introduction of blood into either the upper or lower end of the alimentary tract. The intramuscular injection of whole blood plasma, reconstituted dehydrated serum, and particularly of concentrated red-cell suspensions, and transfusions of blood and plasma have all been followed by highly significant elevations of capillary resistance.

In this article are reported the results of exploratory capillary resistance determinations made before and after certain surgical procedures. Before signs within three hours of the time that the operation was started and after means approximately twenty four hours after the operation. No statistical treatment of the data is required to support the conclusion that in 23 investigated cases a remarkable increase in capillary resistance followed surgical operation.

In 6 cases of simple fracture determinations of capillary resistance were made within twenty four hours after the fracture and between five and seven days later. No case was operated upon or received blood or plasma transfusions between the time of the two observations on capillary resistance. In all cases the capillary resistance was significantly higher at the first observation than at the second a finding which supports the results described following surgical operations and which shows that similar increases in capillary resistance follow injuries which do not involve the skin surface.

This increase appears to be independent of the age and sex of the patient, of the anesthetic employed and of the nature of the operation performed. No information is provided by this investigation as to the mechanism of this striking phenomenon for which at present no physiological explanation is available.

JOHN E. KIRKPATRICK, M.D.

BLOOD; TRANSFUSION

Pedley F. G.: Hemoglobin Concentration in College Women. *Canad. M. Ass. J.*, 1944, 51: 331.

The hemoglobin concentration of 864 college girls is given. The estimations were made in the photoelectric colorimeter which is believed to give more consistent results than the conventional hemoglobinometers.

In view of the fact that 40 per cent of the girls showed hemoglobin levels of between 14 and 16 gm. per 100 cc. of blood it is suggested that a "good" if not "optimum" level of hemoglobin in women should be set at about 15 gm. per 100 cc.

The significance of small deviations below this level in terms of efficiency and health is not known.

HOWARD A. MCKNIGHT, M.D.

Propp, S., and Schwind, J. L.: Sternal Puncture as a Practical Diagnostic Procedure. *Ann. Int. M.* 1944, 21: 580.

The author considers the sternal marrow puncture an extremely useful and practical procedure in the study of diseases of the blood and in cases in which the possibility of such diseases enters into the differential diagnosis. However it should be used only on definite indications. A sternal puncture should always be made when (1) the diagnosis is in doubt and a disease usually showing a typical myelogram cannot be excluded—for example an agranulocytosis in which there is the possibility of aleukemic leukemia (2) the etiology of the peripheral blood findings

is obscure ("aplastic" anemia or idiopathic anemia) (3) other means of diagnosis short of surgical biopsy have failed. In addition, a sternal puncture may be made to (1) save time if a specific marrow picture is likely to be present (2) obtain information concerning prognosis (3) determine response to treatment, as in a pernicious anemia which does not seem to benefit from liver-extract therapy and (4) determine the type of a stem cell leukemia when this cannot be done with certainty from the peripheral blood.

The needles are of the 18-gauge spinal puncture type with a heavy finger grip and a stylet. They are cut so that the needle portions are 2 1/2 and 1 cm. in length. The two longer needles are used for adults the choice depending upon the build of the individual, and the smallest one is used for infants and children. The shortness of the needles precludes the possibility of accidental perforation into the anterior mediastinum and prevents bending of the shaft of the needle during its insertion. The puncture is made in the midline of the body of the sternum at the level of the third costosternal articulation. This site is easily found even in obese patients, by using the sternal angle which marks the second rib as a reference point. In children it is advisable to do the puncture in the third interspace because in some individuals the first and second sternbrae do not unite until adult life is reached. When properly carried out under local anesthesia sternal puncture is not a very painful procedure. The puncture needle is inserted vertically and the outer table of the sternum is pierced by a rotary movement of the needle under firm pressure. When the needle is firmly fixed in the sternum, the stylet is removed a tuberculin syringe is attached to the needle and aspiration is attempted. If no marrow fluid appears, the stylet is replaced the needle is advanced a little farther and aspiration is again tried. From 0.1 to 0.2 c.c. of marrow fluid is withdrawn.

The most satisfactory portion of the specimen for study is that which enters the needle last and therefore this is used in making the first smears which are stained with Wright's stain.

Sternal puncture cannot be substituted for a complete clinical investigation of the patient. Indeed the more thorough the work-up of the patient, the easier and more valuable is the interpretation of the puncture. Most diseases unfortunately do not show specific changes in the marrow from which a definite diagnosis can be made, but much clinically valuable information can be obtained which is of aid in the differential diagnosis and subsequent handling of the patient. Diagnosis should be made only from specific myelograms and a negative result does not absolutely preclude the presence of a given disease because of the possibility that a representative sample of marrow may not have been secured or atypical variations in the pathological lesions of the disease may be present. Punctures which yield no marrow cells upon aspiration should be followed by a trephine biopsy if the diagnosis can

be reached in no other way and no contraindications are present.

In the authors' series of 140 cases, 65 per cent of the 74 indicated punctures gave information of clinical value, and the diagnosis was made in 16.2 per cent when this was impossible by any other method short of biopsy. JOSEPH K. SARAT, M.D.

Weiss, D., and Haines, K. E.: Burn Trauma Precipitating Acute Leucemia or a Leucemoid Condition. In *J M Sc* 944 203 490.

The authors present an interesting case of a young colored soldier who up to the time of being severely burned was apparently healthy and able to carry out the usual arduous duties of a soldier. On admission to the hospital his blood picture was normal as time progressed his burned areas appeared to be healing satisfactorily but more or less rapidly as recovery seemed certain his blood picture became chaotic and suggested acute leukemia or a leucemoid condition. Weiss and Haines briefly discuss the infectious theories regarding the etiology of leukemia.

The pertinent contribution of this case report is the possible etiology in relation to the burn. Evidence and opinions that trauma is a possible etiological factor in acute leukemia are cited.

J. M. MORA, M.D.

Adams, W. E., Thornton, T. F., Jr., Allen, J. G., and Gonzalez, D. E.: The Danger and Prevention of Citrate Intoxication in Massive Transfusions of Whole Blood. In *Surg* 944 120 656.

The value of blood transfusions in improving and widening the scope of surgery has become more and more appreciated. They are used to prevent and treat shock and anoxia. Another purpose is the improvement or maintenance of blood plasma proteins, a factor of importance in the healing of wounds and a satisfactory postoperative convalescence.

Actual determinations made following some thoracic operations have revealed that 1,500 cc. of blood are an average loss in lobectomy and pneumonectomy while in some instances it is as much as 3,000 cc. Because of this an attempt has been made to replace the blood with an equal amount of whole blood or plasma in order to maintain the circulating blood in a normal state.

Because of warnings against the too liberal use of citrate in large transfusions experiments were planned by the authors to test the influence of various factors which might contribute to the harmful effects of massive transfusions of citrated whole blood. The methods used are described. The effect of sodium citrate on normal dogs was studied in 23 animals. From these experiments the authors concluded that normal dogs tolerate approximately 0.25 gm. of sodium citrate per kilogram of body weight (sufficient to cover 60 per cent of the estimated blood volume with a 0.41 per cent solution) when not injected too rapidly (over a period of twenty minutes or longer).

The influence of calcium gluconate on citrate intoxication in normal dogs was studied in 4 animals. These experiments demonstrate that when locally available is made available, a higher concentration and a larger amount of sodium citrate may be given more rapidly without fatality (1 gm. per kilogram in from twenty to twenty-eight minutes).

Eleven dogs were studied for the effect of autotransfusions with citrated whole blood following hemorrhages of from 20 to 60 per cent of the estimated blood volume. The authors found that normal dogs will tolerate replacement with citrated whole blood after severe shock due to hemorrhage of from 20 to 60 per cent of the estimated blood volume (with sodium citrate to cover from 35 to 60 per cent of the blood volume) when given over a period of from twenty to thirty-five minutes.

Four dogs were studied for the influence of calcium gluconate on autotransfusion with citrated whole blood following hemorrhages of from 26 to 70 per cent of the estimated blood volume. It was noted that a larger blood loss and replacement with a higher concentration of sodium citrate given more rapidly (from three to thirteen minutes) was tolerated when calcium gluconate was administered.

In a study of 11 animals the authors found that bleeding of from 30 to 50 per cent of the estimated blood volume and replacement with a similar amount of physiological saline solution with or without the addition of calcium gluconate, was well tolerated when administered in from three to twenty-five minutes.

Simultaneous bleeding and replacement of blood loss with prepared citrated (0.41 per cent) whole blood were studied, first without the use of calcium gluconate and later with it. Four animals were used in the first group and 8 in the latter. It was concluded that normal dogs tolerate simultaneous bleeding and transfusion of citrated whole blood amounting to as much as from 75 to 125 per cent of the estimated blood volume. When calcium gluconate was added as much as 200 per cent of the estimated blood volume was removed and replaced without fatality.

The authors found that large doses of citrate were necessary to produce harmful effects and that the rate of injection was an important factor. When the rate of injection of sodium citrate alone or as citrated blood was comparable to transfusions of 1,000 cc. of blood per hour in man, as much as 0.24 gm./kgm. of body weight or sufficient citrate for use in 60 per cent of the estimated blood volume, was safely tolerated. If the administration was over a very short period (sufficient citrate for 60 per cent of the estimated blood volume given in from ten to twelve minutes) the action was usually fatal. No untoward effects were noted when physiological saline solution was used after severe hemorrhage. It appeared to make little difference when calcium gluconate was given with the saline solution.

These experiments would seem to indicate that animals in which shock has been produced are able

to tolerate citrated whole blood somewhat less well than animals in which shock is prevented by the administration of citrated whole blood during the bleeding period. The rate of administration should be somewhat slower in the patients in whom severe shock has resulted from massive hemorrhages.

The picture of citrate intoxication was similar regardless of the type of experiment. Alterations in the blood pressure tracings were observed for several minutes prior to a rapid terminal fall. Some change in respiratory activity was usually present before fatal intoxication. Respiratory failure was never observed prior to cardiac failure. Definite tetanic contractions occurred in some of the second group of animals when citrate intoxication occurred. Eye reflexes were very sluggish. The color of the blood was very dark and gas analyses revealed the oxygen to be as low as 3 or 4 volumes per cent. Severe acidosis was observed.

The use of calcium gluconate in preventing or treating citrate intoxication both in normal animals and in those that had had a loss of blood was extremely effective. The abnormal findings described soon returned to normal. The amount of calcium usually employed in animals weighing from 7 to 14 kgm was approximately 4 gm. (20 cc. of a 20 per cent solution) for the replacement of from 60 to 100 per cent of the estimated blood volume.

The authors conclude that massive transfusions of citrated whole blood for the treatment of extreme shock (blood pressure of from 30 to 45 mm. of mercury) produced by hemorrhage of as much as 60 per cent of the estimated blood volume were safely tolerated in dogs when the replacement of the blood loss was made during a period of twenty minutes or longer. When bleeding and transfusions were conducted simultaneously an average of 115 per cent of the estimated blood volume was exchanged during a period of seventy minutes before the animal expired. This would correspond to a transfusion of 7,840 cc. of blood given during the same period of time for a man weighing 70 kgm. When the rate of bleeding and transfusion was less rapid a larger volume was exchanged without reaction. Thus, a larger margin of safety is present even in massive transfusions of citrated whole blood or plasma when the administration is at the maximum rate currently employed in man (1 000 cc. per hour).

HERBERT F. THURSTON, M.D.

RETICULOENDOTHELIAL SYSTEM

Ballay H. A. and Schreiber, S. L.: Delayed Rupture of the Spleen. *Am. J. Surg.*, 1944, 66, 4.

Rupture of the normal spleen has greatly increased in frequency and is not considered the rarity it was formerly thought to be. The literature has recorded consistent increases explaining that they are due to greater industrial activity and greater use of the automobile.

The spleen is involved in 47.6 per cent of all subcutaneous injuries to the abdomen either isolated or

Fig. 1. Top: Diagrammatic representation of types I and II of splenic rupture, both leading to rapidly progressive hemorrhage. Variations of type I are a complete severance of the pedicle and a complete disruption of the spleen. Bottom: Diagrammatic representation of types III and IV of splenic rupture. Type IV is the lesion commonly responsible for the development of a perisplenic hematoma. (From Roettig et al.) (Courtesy of American Journal of Surgery.)

complicated with other injuries. Therefore injury to the spleen outranks trauma to the liver and to the kidney. Yet the diagnosis is too frequently missed. This pertains perhaps mostly to the delayed type of splenic rupture. All too frequently the diagnosis is made at autopsy.

Difficulties in the diagnosis have been described as follows: (1) absent visible signs of injury to the anterior abdominal wall which permits the patient as well as the physician to disregard the early mild symptoms, since the reasoning is that the trauma sufficient to rupture a spleen should cause more visible signs of injury; (2) the history may be misleading, especially in those patients who have had severe or violent muscular activity some hours preceding the onset of symptoms; (3) the shock which is present is thought to result from associated injuries to the head, chest, or extremities or to alcoholism that is the patient may present more obvious symptoms from his associated or complicating

injuries and (4) the recession of symptoms lulls the observers and patient into a false sense of security. Added to these difficulties is the delay of the patient in seeking medical care—that is, the time consumed in getting the patient to the hospital or the doctor to the patient from the onset of the accident—or the time consumed in combating shock so that the symptoms of ruptured spleen may recede or become quiescent—or the difficulty in making the diagnosis in the presence of multiple injuries, which can well explain why a rupture of the spleen can be overlooked.

The authors report a case history of one of their own patients who was suddenly seized with an acute upper abdominal pain and who exhibited a tender right abdomen. X-ray examination was negative. A diagnosis of perforated peptic ulcer was made and at operation a ruptured spleen was found. No history of violence was obtained. Such cases are among the most difficult as regards preoperative diagnosis.

Five types of splenic rupture are described.

Type 1 is a complete fragmentation of the spleen into two or more parts or a complete tearing of the

spleen from its pedicle. This results in a massive hemorrhage and in many instances sudden death.

Type 2 represents a large tear at or near the hilum. This gives rise to grave hemorrhage.

Type 3 is characterized by one large tear or multiple tears about the periphery of the spleen. This type leads to slow and persistent development of the signs of intra-abdominal hemorrhage.

Type 4 is characterized by a solitary tear at the periphery. Symptoms of this type are of recovery after an initial injury and after a period of relief the patient goes suddenly into shock with all the signs and symptoms of a concealed hemorrhage and gradually becomes worse.

Type 5 is a subcapsular hematoma and corresponds to Blocker's Type 2—intrasplenic or subcapsular hematoma. This may be the so-called spontaneous cure group of Wright and Prigot, but, if so, this spontaneous cure is not a fact as no instance of healed splenic hematoma has been found.

The authors present the theories and observations relating to splenic rupture as listed by Zalarski and Harkins.

BENJAMIN GOLDBERG, M.D.

SURGICAL TECHNIQUE

WAR SURGERY

Rob. C. G. : The Conservative Treatment of Abdominal Wounds. *Lancet* Lond. 1944, 247 521

This article is based on 141 war wounds with definite abdominal signs. Laparotomy was performed in 98 with 33 deaths. Ten of these laparotomies were found to be unnecessary and 1 of the deaths occurred in this group. Laparotomy was not performed in 43 cases and no deaths occurred among these 43 cases.

In deciding whether or not cases required laparotomy the staff was guided by the patient's general condition, especially his blood pressure and pulse rate. Due allowance was made for the effects of morphine which had been administered previously. Other signs especially considered were tenderness and rigidity, absence of respiratory movements and silence on auscultation.

It was found that the ordinary signs and symptoms of an acute abdomen do not hold in gunshot wounds.

Conservative treatment consisted primarily of observation. Operative treatment was performed in most cases through a paramedian incision. Treatment consisted of suturing all perforations of the alimentary tract proximal to the ileocecal valve. Resection was necessary in 10 cases with 4 deaths. Most of the wounds of the large intestine were exteriorized.

Bladder wounds were sutured and suprapubic cystostomy was performed. Peritoneal drainage was not used in most cases. Wounds of the spleen were treated by splenectomy. Wounds of the liver were sutured or packed. Renal wounds were treated conservatively. Nephrectomy was necessary in 3 cases.

Penicillin and gas-gangrene serum were used prophylactically. Postoperatively blood or plasma, or glucose-saline solution was used. Gastric suction was used when indicated.

The sulfonamides and morphine were used liberally. Blood was administered to most patients postoperatively.

All patients were retained from ten to fourteen days before evacuation.

Residual intraperitoneal abscesses were rarely present. The sulfonamides were given credit for this finding.

Eighteen deaths were ascribed to shock and hemorrhage. 6 were due to peritonitis. 3 patients were beyond visceral repair. Three deaths were due to pulmonary emboli, while cerebral abscess and acute pancreatitis caused 1 death each. In 1 case a high gastric perforation was missed. Six patients died after admission but before they could reach the operating room.

In the cases with recovery the average time between injury and operation was eight and four tenths hours. In those with death from shock, the

average time was fifteen hours. In those with death from peritonitis the average time was twenty five and one-half hours. RICHARD J. BROWNE JR., M.D.

Weddell, J. M. : Surgery in Tunisia. *Brit. M. J.* 1944, 2 459.

The author describes the general lay-out of the medical units with the British forces during the Tunisian campaign and indicates some of the points of interest and lessons learned during that period.

The Thomas splint usually with the metal boot clip was universally and correctly used. Tourniquets were rarely seen and rarely necessary. There was a tendency at times to overdo the injections of morphine. If patients passed through several posts they were sometimes found to have received as much as a grain of morphine by the time they arrived at the operating center.

The question of blood versus plasma has been much discussed. The experience of the British surgeons was that patients with severe injuries could be restored to a reasonable condition with plasma, but that they would not then stand an operation of one hour's duration without blood. Blood was neither wasted nor used excessively. In attempting to forecast the number of patients who will require resuscitation, various factors should be borne in mind. If the unit is dealing with first priority cases, a large proportion (probably over 50 per cent) will require resuscitation. If with second and third priorities there will not be so many. The longer the time lag in the receipt of the cases the more will require resuscitation. Local conditions, cold wet weather, a long journey over rough roads will also have an effect.

Apart from the use of ether for laparotomies and multiple wounds, most patients were anesthetized with pentothal. The advantages of this drug are the rapidity of induction and the freedom from post-anesthetic vomiting—a point of the greatest importance in the busy postoperative wards. Pentothal with oxygen was very satisfactory for the thoracic cases.

In the early stages of the fighting cases were observed from which too much skin had been excised. A few attempts at primary suture, too tight packing of wounds, and insufficient division of the deep fascia were also noted. Adequate division of the deep fascia was found necessary especially in wounds of the buttock, calf and popliteal space.

Extremities and joints. For transport during evacuation some form of the Tobruk plaster was universally used for the lower limb. Generally the limb was encased in plaster with slits for the traction strapping and fixation of the limb to the Thomas splint with plaster bandages. The plasters were always padded and split. For the upper extremity the U plaster from the nape of the neck and including the forearm, was most used and proved satis-

factory The immobilization of extensive soft tissue wounds had been advised, but was perhaps not carried out as often as it might have been. Traction for wounds of the knee joint was occasionally found to have been omitted. The usual faults in plaster work appeared from time to time carrying the plaster beyond the proximal crease of the palm so that stiffness of the metacarpophalangeal joints and fingers resulted. Lack of instruction to the patients to move the fingers and toes continually faulty position of the ankle and foot.

Abdomen The treatment evolved in the Middle East was amply confirmed, suture, when possible rather than resection, exteriorization and colostomy for wounds of the colon and rectum, gastric suction and intravenous therapy as a routine and retention of cases for a minimum of ten days.

Chest Conservative surgery (wound excision and closure of the open pneumothorax) with early aspiration was the rule and proved satisfactory. Great relief of dyspnea was noted after the early aspirations of hemothorax fluid. Many breathless shocked patients were greatly relieved by being propped up, these patients travel better in ambulances and trains when so positioned. The advantage of treating the shock by the completely recumbent position does not compensate for the serious respiratory embarrassment caused. In only a few cases was full thoracotomy indicated in the forward area.

Head At the beginning there was some difference of opinion between the general surgeons and the neurosurgeons as to whether the general surgeons should deal with these cases. It was pointed out that in the forward units the general surgeon had no special equipment for this type of work, diathermy was not available, x-ray examination was not always possible and at the time there was only improvised suction. It was therefore accepted that it was better to get patients back to the neurosurgical unit within forty-eight hours if this was possible, for operation there. The sulfonamides (sulfadiazine when available) were always used.

Burns All coagulation treatment was forbidden as first aid. The routine was sulfanilamide and vaselined-gauze dressing. It was confirmed that cases of severe burns travel badly during the first five or six days after injury.

Chemotherapy Sulfonamides were used prophylactically and therapeutically. To begin with, oral doses at four hour intervals had been advised for all wounded. In practice this broke down on the long lines of communication, and the Middle East sulfanilamide label with the two doses at 8 a.m. and 6 p.m. was adopted. Because of the universal use of these drugs both orally and locally it was impossible to evaluate their effect. The general impression was that they were of value in retarding the onset of infection. Also as compared with the last war the appearance and general condition of the men in the base hospitals seemed better. Sulfanilamide, sulfathiazole and sulfapyridine were the forms mainly in use for surgical cases.

Inacrobic infections Tetanus Up to May, 1943, 1 case of generalized tetanus occurred in a German prisoner of war and 1 case of local tetanus occurred in a British soldier. Both recovered. Gas gangrene: Up to May 1943 there had been less than 100 cases. Treatment consisted of early surgery, large doses of serum, and administration of the sulfonamides.

JOSEPH K. NARAT, M.D.

Morris, G. N.: Experiences with a Mobile Surgical Team on an Amphibious Operation in New Guinea. *Med. J. Australia* 1944, 2, 402.

A surgical team consisting of 3 surgeons and 3 orderlies was detached from a general hospital and assigned to service the troops of an Australian Infantry Division in the battles on the Hoon Peninsula. Its function was to provide surgical treatment for the wounded as far forward as possible. This team worked at the main dressing station of a field ambulance, but never was able to function as far forward as the advanced dressing station. It began service with the initial landing at Red Beach in the attack on Lae. It then leaptfrogged to another point on Lae where it served for ten days, and then moved again to partake in the attack on Finschhafen. In the latter landing, the surgical team began operating within an hour of reaching its site on Scarlet Beach. Most of the time it was found advantageous to dig in the operating tent to a depth of 4 feet so as to protect the patients on the operating tables from flying bomb fragments. On many occasions the surgeons were forced to finish operations in the squatting position.

The total weight of the equipment carried by this 5 man surgical team was reduced to 1,000 lbs. Each was packed in 40-lb. lots. The surgical instruments consisted of 12 hemostats, 2 scissors, 2 tissue forceps, skull forceps, amputation saw, scalpels, needles, and 1 set of retractors, all packed in a kettle sterilized. Also 2 sealed Johnson and Johnson drums containing sterile gowns and dressings, 2 primus stoves and 2 gallons of kerosene were carried. These items approximated a 40 lb. pack. Every man carried just enough clothes for a single change. Only 1 standard light weight portable operating table was carried. Other operating tables were made of crude, forked sticks to which the stretcher was attached. Operating tables were looked upon as a convenience rather than a necessity.

This surgical team treated 400 casualties in a period of three months with a maximum of 50 casualties per day. In this group there were 26 abdominal wounds involving either a solid or hollow viscus, or the mesentery. Many of these were multiple wounds. Other major casualties consisted of 16 penetrating chest wounds, 16 penetrating wounds of the skull, 10 compound fractures of the femur, 22 fractures of the tibia, and 13 fractures of the humerus. The most common wound sites were found to be the arms and legs.

The following points of clinical interest were drawn from these cases:

Patients with head injuries who were completely unconscious from a penetrating wound were not worth operating upon, especially if other serious casualties were waiting for emergency treatment. Further it was not advisable to evacuate penetrating skull wounds for a few days. Patients with penetrating chest wounds should be sutured immediately. Aspiration of a pressure pneumothorax with syringe and needle always proved to be a life-saving procedure. In addition to essential surgery for penetrating abdominal wounds, all casualties in this battle area were given quinine intravenously twice daily to combat malaria. In extensive wounds of the lower extremity, incision for gangrene was delayed until thorough débridement had been made. In 8 cases main-stem arteries were ligated—4 brachial arteries, 1 hypogastric arteries and 3 femoral arteries. In this series, only 2 cases of gas gangrene developed one from a buttock wound and the other from an incomplete débridement. Sodium pentothal given intravenously was the anesthetic of choice. Blood for resuscitation was obtained from combat soldiers of O(IV) blood group. All recipients of blood were given quinine.

B G P SHAYKOFF, M.D.

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Marshall, D. V. Pulsator Treatment of Crush Injuries. *Lancet* Lond., 1944, 247, 562.

Four cases of crush injury which occurred two years ago after an air raid are recorded; the results were unexpectedly good. The Booth respirator was used in their treatment. The author has had no opportunity of trying the method in additional cases.

During the severe raids in the spring of 1941 quite a number of patients having been buried under masonry and extracted after varying periods of time (from four to ten hours) came to hospital showing little in the way of external or internal injuries but soon after their limbs became numb and swollen and about forty-eight hours after admission they suddenly became ill and died the next day or later blood being found in the urine some hours beforehand. One patient's arm was treated for about ten hours in a Booth respirator before she was transferred to a hospital in the country. The patient said her arm felt very much better after the treatments and it recovered quickly. This incident prompted the author to treat all of the crush injuries which came under his care in York in the Booth respirator.

As soon as possible after the diagnosis of crush injury was made the damaged limb or limbs were placed in the respirator and the pulsation mechanism was worked at the slowest rate provided for about half an hour. Four patients received treatment for this period every two or three hours in rotation. The treatment was continued regularly except during sleep until the circulation of the affected parts seemed to be restored as judged by the diminution of pain, return of warmth and color, and loss of tension. All of the patients recovered, and 3 said

that their pain was much reduced by the treatment and that they felt generally better. The patient who was injured least and who was mentally clearest was most emphatic on this point. One woman who was most severely crushed and who complained of so much pain that at first it was thought she had fractured pelvis in addition to her leg injury, did not experience relief and found moving from the bed in and out of the respirator rather trying.

Most of the efforts in treatment have been concerned with preventing renal damage by medication or treatment directed toward relieving the kidneys or preventing the toxin from getting to the kidneys in large amounts after damage has occurred. The treatment is also aimed at preventing changes in the muscle by relieving or improving the circulation at the earliest moment.

It is suggested that the fatal result of the crush injury syndrome may be prevented by prompt restoration of the circulation in the affected part with a mechanical pulsator. JOHN E. KIRKPATRICK, M.D.

Swenson, S. A. Jr., Harkins, H. N., and Grossbeck, H. P.: Pilonidal Sinus. Clinical Experiences with the Rogers Operation in 35 Consecutive Cases. *Am. J. Surg.* 1944, 66, 49.

The authors report their experiences with the Rogers operation in 35 consecutive cases of pilonidal sinus. They state that with this procedure there is complete removal of the diseased tissue, healing takes place in the presence of infection, the rate of recurrence is low and the patient loses little or no time from his work.

Local novocain anesthesia was used in 20 cases; spinocaine in 14 cases and general anesthesia in 1 case. In this series the Bowie cautery was used on hospitalized patients and a modified radio-cautery was used on outpatients. A narrow ellipse of skin was marked out above the sinus tract or cyst. Healing was more rapid in the cases which did not have overhanging edges. The authors state that the use of the cautery knife provides a bloodless field which aids in the recognition of unstained normal tissue.

Diseased tissue is less readily divided by the cautery knife than is normal tissue. The dissection is carried down to but does not divide the diseased tissue in the attempt to remove the tract en bloc. The defect resulting from the removal of the diseased tissue is packed with dry gauze and a small dressing is applied. Outpatients are permitted to go home immediately and they may return to work.

The first change of dressings is carried out on the fifth or the sixth day and a new pack is inserted. This pack is allowed to remain for two days, and on the third day it is removed in a sitz bath. The patient then takes two sitz baths a day applying a dry sterile dressing after each bath. He returns to the clinic twice a week until the terminal stages of healing after which he reports weekly.

Hospital patients are treated similarly. Frequent visits to the clinic are recommended as being more

important during the last few weeks of healing because the whole success of this method of treatment depends upon proper care, preferably by the original operator.

In this series of 35 cases 25 per cent of the patients were females, and 75 per cent were males. The average age was twenty-six years. Seventeen of the patients were from twenty to twenty-nine years. Fifteen patients had known of their lesions for one year or less. 15 had had previous or preliminary treatment. In 24 patients the duration of the drainage was from one week to two months. Twenty-four patients presented only one sinus tract. In 23 patients the inpatient procedure was carried out and in 12 the "out-patient" treatment was given. In the cases of the 3 hospital patients, the average stay was six and one half days. The average number of postoperative visits was 10 and the average healing time in 30 cases was fourteen and one half weeks.

The advantages of this procedure are the low cost, the small amount of tissue removed, and the high percentage of primary cures.

RICHARD J. BERRYETT JR., M.D.

Zintal, H. A., Riegel, C., Peters, R., Rhoads, J. E., and Ravdin, I. S. Intravenous Administration of Dextrose in the Treatment of Patients with Disease of the Biliary Tract. *Arch. Surg.* 1944, 49, 38.

Biopsy specimens of the liver were taken from a group of 58 patients with disease of the biliary tract. Eighteen of these patients received dextrose intravenously before operation while the remaining 40 were controls and received none. The average glycogen level of the liver of the patients who received dextrose intravenously was 6.1 per cent, or 118 per cent greater than the average glycogen level of the control group.

The patients who had moderate hepatic damage, as judged by histological studies and who received dextrose intravenously had an average hepatic glycogen level of 5.7 per cent, or 104 per cent more than the level observed in the control patients. Intravenous administration of dextrose without dietary supplement did not significantly lower the fat content of the liver in the patients observed.

The authors state that the protection of the liver against damage resolves itself into the positive action of protein, the indirect action of carbohydrate, and the negative action of fat. The results of administration of a diet high in carbohydrate and protein, low in fat, and high in calories for five days or more before operation while excellent from the standpoint of reducing the fat content of the liver were not impressive from the standpoint of the degree of elevation of the glycogen level. The average increase of liver glycogen after such a diet in patients with severe hepatic damage was 10 per cent. On the other hand there was no evidence in the patients who received dextrose intravenously that the fat content was significantly lowered.

In the light of these findings, the optimum preparation of patients with hepatic damage for surgery operation would probably be obtained with the administration of a diet high in protein and carbohydrate and low in fat for a period of from five to fourteen days, supplemented by intravenously administered dextrose for a period immediately prior to operation.

Liver glycogen is so labile that if one desires to maintain it at a high level during an operation, intravenous administration of dextrose is fully justified especially during the period of fasting immediately before operation. As much as 45 per cent of the liver glycogen may be lost during the course of a long operation as reported by Ariel Pack, and Rhoads.

HARRIET F. THURSTON, M.D.

Brown, J. B., and Cannon, B.: The Repair of Surface Defects of the Foot. *Ann. Surg.* 1944, 30, 412.

The skin and subcutaneous tissues of the sole of the foot and of the palm of the hand constitute a specialized organ. Skin and subcutaneous tissue transplanted to the sole of the foot from other areas of the body do not constitute a normal sole and there may be difficulty in maintaining them in a satisfactory condition in their new environment and function. Keratosis, warts, cracks and chronic ulcers may appear and cause disability. If nerves are present in the area of the sole, even in free grafts and flap sensation will return.

Small lesions of the foot may produce disability and especially in military service may cause complete loss of a soldier because one of the most important functions of a soldier is lost if he cannot walk.

The preoperative care includes rest, baths, soap and water sulfonamides or penicillin, fine mesh gauze next to open wounds, pressure dressings, and elastic bandaging of the foot and leg. Every effort is made to get these wounds as clean as possible, guided by bacteriological studies. No repair or operation may be even contemplated until all abscesses, dead tendons, fascia, and bone are out of the wound. There must also be good healing power which it support transplanted tissue. Physical therapy is used in all cases.

When a flap is lost, the donor site may be worse than the original lesion. Radical excision must be carried out in widespread scars so that a new blood supply may be developed to support the transplanted tissues. Burns and superficial lesions respond well to free grafts although gunshot and shell-fragment wounds or other deep injuries may require a flap repair. Flaps will not do well where grafts will do well. A distant flap does not bring additional blood supply but just helps the local minute blood supply temporarily. Local flaps bring in their own blood supply and improve the local circulation. Local flaps may deprive another area of a satisfactory covering and may cause loss of important local sensory nerves. Local flaps which uncover important weight bearing points, the heel cord, or the malleoli, should not be used.

The methods of repair include

1. Excision of the scars and immediate resuture. This may be carried out only occasionally because of lack of extra tissue in the foot. Large losses practically always need some type of replacement even though it proves a poor substitute.

2. Free skin grafts may be used if a satisfactory thickness of subcutaneous tissue remains to give support and blood supply. Open wounds on the sole of the foot are subject to severe disabling infections and should be closed as soon as possible. Free grafts may be used to get the wound closed as soon as possible, and later on a flap may be used for permanent closure.

3. Direct local flaps may give excellent repairs of small lesions if important sensation is not interrupted and both the local blood supply and the blood supply of the flap is adequate.

4. Delayed local flaps are the safest form to use locally; at least two stages of operation should be used. Detachment of flaps may usually be carried out in from sixteen to twenty days. In large flaps, partial detachment in 2 or 3 stages may be carried out with more safety.

5. Direct cross-leg flaps may be used if a suitable position can be decided upon.

6. Delayed cross-leg flaps either flat or tubed are safest.

7. Same-leg delayed flaps may be used occasionally they should be tubed rather than flat.

8. Distant turnover jump or caterpillar flaps from the abdomen or flank are a rare necessity.

9. Distant wrist borne flaps are used occasionally. Tubed flaps need a special type of application. Large long tubes should be attached in a normal site close to the defects.

One of the most difficult problems in postoperative care is to keep the patient off the new repair for a sufficient length of time. Local trauma and extremes of temperature should be avoided.

A wide knowledge of the faults of flaps and grafts must be acquired so that these difficulties may be guarded against. Ordinary skin will not change into normal foot tissue and continued protection clean lines careful observation and pads are necessary. Prevention is better than cure. Some surgeons believe that only sole tissue should be used on the sole. The end results in skin repair of the foot vary from poor to practically normal. Prolonged disability has been relieved by single procedures.

RICHARD J. BIGNETT JR., M.D.

Young, F: Skin-Graft Fixation by Plasma-Thrombin Adhesion. *Ann. Surg.*, 1944, 120: 450.

The author notes that the survival of a free skin graft depends upon the rapid establishment of an adequate circulation. During the first twelve to twenty four hours after transplantation it is generally believed that there is an osmotic flow of plasma into the graft.

The early vascularization of a skin graft may be delayed or prevented by numerous factors. The graft may be too thick or of too great area for the

vascularity of the bed in question. A full thickness skin graft will rarely take on a granulating surface. Full-thickness grafts when applied to fresh surgical wounds have a higher percentage of take when the graft is from a thin skin area such as the groin inner surface of the upper arm, or eyelid. It is also well known that full thickness grafts have a higher percentage of take than those of large square area since in the smaller graft the peripheral circulation established is relatively of more importance. In general the thinner and smaller the graft the higher percentage of success.

The character of the bed is important for the survival of the free skin graft. A high percentage of take cannot be expected on an avascular fibrotic bed. The percentage of take is usually lower on a soft yielding irregular surface than on a smooth firm bed.

There are numerous untoward effects which can prevent complete continuous contact. The graft may slip off of the recipient area or it may be lifted off the bed by bleeding. Infection may cause the formation of purulent exudate under the graft and on irregular surfaces the graft may be stretched across depressions and the bed may move unless adequately splinted.

In the past a high percentage of takes has been obtained by careful attention to many details one of which was the use of compression dressings to keep the graft firmly in contact with all irregularities of the bed. Joints were splinted and unlay forms used on parts where splinting was not possible.

Fixation of split thickness grafts on either fresh surgical wounds or granulating beds can be accomplished by the precipitation of fibrin between the graft and the bed by adding thrombin to plasma. The rate of fibrin formation can be adjusted to any speed desired by increasing or decreasing the concentration of the thrombin solution.

The author states that 22 separate free split thickness skin grafts were applied with the use of fibrin and without pressure dressings or suture. On extremities where the part could be suspended no dressing whatever was used. On other parts merely a loose dry gauze for protection was applied. The amount of skin transferred at one operation has varied from 4 square inches to 200 square inches. The majority of cases were wounds of considerable dimension usually exceeding 30 square inches. The exact procedure followed in making the graft is given in detail as well as the preparation of the fibrin.

Because the percentage of take normally expected on fresh wounds is higher than on granulation tissue, the author divides these cases into two groups. Of 12 patients with a primary graft 8 had free grafts placed on fresh surgical beds. There was no loss in this group. In each case the graft take was complete. The 4 remaining patients in whom the bed was fresh had traumatic contaminated wounds. In these the percentage of take was 48. The figure was lowered by total loss of the graft in 1 instance. In the 10 granulating wounds a 59 per cent average take was

estimated. In 2 instances the graft was lost completely. In all of the instances it was evident that the loss of graft was due to the accumulation of fluid under it. Large bulbous areas form most of which, when opened, are found to contain purulent fluid.

On fresh surgical beds the percentage of take of free skin grafts is ordinarily high, and fixation by plasma thrombin adhesion seems to afford an easy method of obtaining the usual high percentage of take. However it is the impression of the author that in infected wounds the loss of grafts is considerably greater when they are applied by this method than when compression dressings are used. This applies to contaminated fresh wounds as well as to granulating beds. Infection is sealed under the graft, drainage is poor and the result is a purulent collection under the graft which prevents vascularization. The greatest loss is at points of movement. This could be prevented by splinting. Small-size thin grafts take better than large thick sheets. It is probable that the mere application of the dressing would produce as high a percentage of take alone.

In conclusion the author states that he believes the method is useful (1) in application of grafts on fresh surgical beds, (2) in holding grafts in position while compression dressings are applied and (3) in applying small grafts such as pinch grafts for which compression dressings are ordinarily not used.

HENRY F. THURSTON, M.D.

Webster J. P.: Refrigerated Skin Grafts. *J. Surg.* 1944, 20: 431.

Refrigerated grafts are seldom used in surgery today although the technique is simple and its application has widespread uses. It is of special value in grafting young, debilitated, or extensively burned patients. The source of the grafts may be cadavers, amputated limbs as homografts or autografts, or the usual donor areas on trunk or limb of the patient himself or of others. Only autogenous skin grafts may be expected to survive permanently.

The procedure has been employed 36 times on 23 patients at the author's clinic during the past twelve years. All of the grafts lived if the recipient areas were suitable and if the grafts were autogenous and were not refrigerated for more than three weeks. In the author's experience those refrigerated over this period failed to survive. No homograft persisted permanently although those refrigerated within the three-week period survived longer than those preserved beyond this time. Lyophilized skin was grafted in 1 case with partial but definite success after seventeen days of refrigeration. This procedure gives promise of being improved and of value. With a modified technique it may be possible to graft lyophilized skin with even greater success and beyond the three-week period of refrigeration.

The refrigeration of skin should be more widely used (a) to store excess remnants of grafts for possible future use, (b) to delay grafting until suitable conditions of the recipient area prevail and (c) to

divide long hazardous operations into two or more less taxing stages. By this procedure the plan of operations may be facilitated and lives may be saved.

LOUIS T. BYARS, M.D.

Crooke A. C., Morria, C. J. O. R. and Bowler R. G.: Plasma Volume in Traumatic Shock. *Brit. M. J.*, 1944, 521.

The plasma volume (by the Evans blue dye method) hemoglobin and hematocrit were measured in a series of patients suffering from traumatic shock. Corrections and technique modifications were made to overcome anomalous dye concentrations in the plasma due to turbidity, hemolysis, and the effect of morphine and hyoscine. A reduction in plasma volume was characteristic during shock and was proportional to the severity of shock. The test was most significant when determined early.

In the severe cases reduction of the plasma volume averaged about 2 per cent of the body weight. In this series the author did not confirm Moon's correlation of shock with hemoconcentration as manifested by increased values for the hemoglobin and hematocrit cell volume. Rather a reduction in the hemoglobin concentration was noted. This did not parallel the fall in plasma volume, but continued to fall as water was withdrawn from the tissues into the circulation, and became most pronounced after the plasma volume returned to normal. The conception of hemoconcentration in shock, according to the author, originates from the viscid, cyanosed appearance of the blood when examined with the Tiselius electrophoretic apparatus is not found to be correct.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Kendry W. E.: The Prognosis in Acute Hematogenous Osteomyelitis with and without Chemotherapy. *Surgery* 1944, 16: 477.

The mortality in acute hematogenous osteomyelitis before chemotherapy was 23 per cent on the average, 46 per cent in the toxic cases and about 3 per cent in the nontoxic cases. After sulfonamide therapy was introduced it was 3.5 per cent.

Previous to the use of the drug, early bone decompression was almost prohibited by the severe mortality. Yet early bone decompression yielded the best results from the standpoints of the later integrity of the bone and function of the limb.

Incision down to the bone, aspiration, or withholding operation either before or after the administration of sulfonamides has not given as satisfactory results as early bone decompression. The new drugs, by controlling the initial septicemia and that which may follow operative intervention, have not allowed safe, early procedures.

The sulfonamide drugs have not proved of value so far as the local pathological process is concerned. One must still depend upon operation for the best results.

This study has been based on the reported experiences of surgeons with 3 176 cases of acute hematogenous osteomyelitis

BENJAMIN GOLDMAN, M.D.

Eliass, D. G. Fuller A. T. and Walker J.: New Drugs Active in the Chemotherapy of Experimental Gas Gangrene. *Lancet* Lond. 1944, 247 553.

Two new drugs p-methylsulfonfylbenzamide hydrochloride (V187) and p-methylsulfonfylbenzylamine hydrochloride (V335) have been synthesized and found to have a potent local chemotherapeutic action in experimental gas-gangrene infections in guinea pigs. Their action is not inhibited by p-aminobenzoic acid.

An extended study of V187 has demonstrated its effectiveness against clostridium welchii, oedematis, and septicum infections. It is well tolerated when given intramuscularly in therapeutic doses. In vitro and in the mouse V187 is as effective against sulfanilamide-resistant streptococci as it is against sulfanilamide-sensitive strains.

In guinea pigs V187 is rapidly absorbed and excreted after intramuscular and intraperitoneal administration. Given orally it is but poorly absorbed.

HAROLD C. OCHSNER, M.D.

Tate, B. C., and Klorofaj I. Sulfonamide Dermatitis; Further Observations. With Special Reference to Treatment and Prevention. *Lancet*, Lond. 1944, 247 553.

In a previous article the author described epidermal sensitization caused by the local application of sulfonamides to the skin. A procedure for desensitization was outlined but the attendant reactions were often extremely severe. The method has now been modified so that complete desensitization is achieved with a minimum of discomfort. A means of preventing this type of sensitization has also been devised. Nearly all of the authors' patients were sensitized originally to sulfanilamide possibly this drug produces a wider range of sensitization than sulfathiazole.

The original procedure was to give relatively large doses by mouth daily and continue giving them in spite of the resulting eczema until the reaction subsided. It became apparent, however, that the quantity of drug required varied with the degree and extent of sensitization and it was also found that there is a threshold dose for each patient below which no reaction occurs and amounts slightly in excess of this produce only mild symptoms. Therefore, it seemed probable that a dose between the minimum threshold dose and that producing a maximum reaction would desensitize with little discomfort to the patient provided treatment were sufficiently prolonged. Experience has confirmed this supposition and the method has been successfully employed in 30 cases.

The correlation between the degree of sensitization and the quantity of drug required was more ap-

parent with the intermediate doses than when large doses were employed. A point of equal importance is the duration of treatment, e.g. 3.0 gm. spread evenly over two or three weeks produce far more complete desensitization than a larger dose given in one day.

Treatment should not be started until any eruption from previous contact with, or administration of the drug has disappeared otherwise symptoms may be unnecessarily severe. Exposure to direct sunshine may greatly aggravate the reaction and must be avoided. A check on the leucocyte count is of course, advisable.

If desensitization results from neutralization of the antibody it should be possible to prevent sensitization by using up the antibody as fast as it is formed. It should indeed be safe to apply the drug locally provided it is given simultaneously by mouth in adequate doses this hypothesis can be proved only by treating sensitized patients in this manner.

The phenomena of this type of sensitization are most easily explained although the explanation is not necessarily correct, by the assumption that some new substance is formed by the epidermis to which it remains fixed. In accordance with common usage this hypothetical substance has been called antibody.

Desensitization presumably results from neutralization of the antibody with allergen. Strongly supporting this hypothesis is the correlation between the degree of sensitization and the quantity of allergen required for desensitization and, more conclusive still the disappearance of sulfanilamide from the blood after its administration to a sensitized patient. However re-sensitization and reappearance of the drug in the blood after too brief treatment show that the reaction between allergen and antibody (simple neutralization as between acids and bases) is a reversible one which is governed by the law of mass action the products of which are only slowly eliminated.

The time required for excretion of the allergen-antibody compound seems to be about fourteen days because, for complete desensitization this is the period over which, it has been observed, the drug must be continued after a large increase of dose has failed to cause symptoms—i.e. presumably after the whole of the antibody has been neutralized. The rate of this excretion may vary in different subjects hence the authors have insisted on a final test of one large dose.

The constitutional symptoms which accompanied desensitization in some cases (rigors raised temperatures fainting blood changes) are essentially manifestations of anaphylactic shock. Their occurrence does not mean however that other organs besides the epidermis were sensitized.

Although no evidence of systemic sensitization has so far been encountered there is no guarantee that it will not develop and the question arises whether this risk should be taken. For most in factive dermatoses local sulfonamide therapy is not superior to other methods of treatment in the

authors' experience but there are instances in which it seems to be of great value and since the main objection to it has been removed by preventive oral therapy, its employment in carefully selected cases is considered justifiable.

The statements in this article are confined to epidermal sensitization to the sulfonamides but the method of desensitization has proved equally successful in acriflavine and boric-acid dermatitis. The authors believe that the principles mentioned are applicable to the wider field of allergy in general.

JORDAN E. KIRKPATRICK, M.D.

Vlter C. F., and Blankenhorn M. A.: The Toxic Reactions of the Newer Sulfonamides. *J. Am. M. Ass.* 944 6 69

In the past four years 1,036 patients in the medical wards at the Cincinnati General Hospital have been treated with sulfathiazole, sulfadiazine, sulfapyridine, sulfaguanidine and succinylsulfathiazole. Sulfapyridine is now considered obsolete and is no longer used in this service. Sulfanilamide is rarely employed and only a preliminary report can be given on sulfamerazine since its use has been recent. This particular study was undertaken to determine the relative incidence of untoward reactions to the various drugs and the relation of the mild and readily recognizable symptoms to severely toxic or lethal reactions. Difficulties were encountered in this evaluation because many patients admitted to this service are critically ill as the result of acute infection or they are in a moribund state of chronic disease and thus the differentiation of symptoms due to drug from those due to disease is difficult. Also the drug is usually discontinued at the first sign suggestive of sulfonamide toxicity. Consequently the course from early and mild to late and severe symptoms can rarely be followed.

Unfortunately there is no absolute method, short of discontinuing the sulfonamide, of differentiating such fever from that produced by the infection for which the drug is given. Frequently, however, there are clinical signs of resolution of the infection, or one is aided by the appearance of skin manifestations.

Skin lesions usually appear between the second and tenth days. Sulfathiazole usually produces a tender erythema nodosum, most frequently found on the extensor surfaces of the extremities and on the face. Sulfathiazole may also produce a morbilliform erythematous rash, either localized or widespread. The skin lesions may become pustular with continued administration of the drug.

Conjunctivitis frequently associated with erythema nodosum, occurred only in patients treated with sulfathiazole. It occurred between the fifth and fourteenth days and was bilateral in all but 1 case. The erythema and moderate edema of the bulbar conjunctiva may be accompanied by burning of the eyes and photophobia.

Nausea and vomiting, distressing symptoms that contributed to the discarding of sulfapyridine, occur infrequently with sulfathiazole and rarely with sulfa-

diazine. They usually appear after the first dose of the drug, in contrast to similar symptoms which may appear later as a result of uremia due to sulfonamide nephrosis or tubular obstruction. It is usually possible to change immediately to another sulfonamide with prompt relief of the emesis.

Polyneuritis, which is usually asymmetrical, has a remarkably high incidence. Its onset with pain, burning numbness or tingling has occurred as early as the seventh day of treatment and perhaps as late as six months after a course of sulfonamide.

Delirium is difficult to attribute to sulfonamides, since it occurs so frequently in febrile disorders. As a rule, it occurs in association with other toxic manifestations of the drugs, particularly renal complications.

Polyarthritides and arthralgia appeared in a small number of the cases between the second and tenth days.

Alterations in the blood and bone marrow are noted 11 times with sulfathiazole, once with sulfapyridine and not at all with sulfadiazine. These reactions may occur at any time in the course of therapy. Leucopenia gives no clinical sign. Thrombocytopenia is, of course, usually associated with hemorrhagic phenomena, hemolytic anemia, jaundice and agranulocytosis with dirty ulceration of the mouth and pharynx. None of the toxic symptoms are of particularly deadly portent. Most of them disappear within one or two days after discontinuance of the sulfonamide, except that neuritis may not. Leucopenia may disappear even while treatment with the sulfonamide continues. When the onset of peripheral neuritis occurs during treatment, the necessity of treatment must be weighed against the possibility of a persistent neuritis after recovery. Thiamine has not cured or prevented the form of neuritis.

The most troublesome toxic symptoms center about the kidney and the urinary tract. These have been the most dangerous to the patient and most difficult to diagnose in the early stages. They appear in two separate forms but may overlap. The one is a mechanical obstruction of the renal pelvis or ureter by crystals, the other is injury of the secreting portion of the kidney.

Sulfonamide nephrosis, characterized by drug retention and a rising blood-urea nitrogen may or may not be accompanied by oliguria and anuria and by albuminuria. It has occurred in patients receiving sodium bicarbonate. It may occur in conjunction with a systemic picture of encephalopathy, myocarditis, hepatitis, anemia, leucocytosis, and fever, and is readily confused with Weil's disease when the history of sulfonamide ingestion is lacking. It appeared in 10 of the cases collected and the smallest dose of drug (sulfathiazol) was 6 gm. The anuria noted regularly between the first and fifth days that the first manifestation was a rising blood-urea nitrogen level.

The treatment of renal complications must suit the individual case. Because of the frequency of

which renal complications occur daily determinations of the fluid intake and urinary output and frequent examinations of the urine for erythrocytes and of the blood for the drug level and nonprotein nitrogen should be routine procedures. For hematuria the urine should be alkalinized promptly by the administration of sodium bicarbonate and fluids should be administered to bring the urinary output to at least 1000 cc. per day. If oliguria or retention of drug or nonprotein nitrogen develops the fluid intake should be increased, but if improvement does not result the drug should be discontinued. Ureteral catheterization is indicated if anuria is preceded by hematuria and renal colic.

The value of routine alkali treatment concomitant with the sulfonamides is still open to question. Although it is true that sulfonamides are more soluble in alkaline solutions and consequently might have less opportunity of depositing themselves in the genitourinary tract, the increased rate of excretion tends to reduce the blood level of the sulfonamide to below effective range.

With advanced age and renal disease, sulfonamides should be prescribed cautiously and the treatment followed carefully. With the onset of persistent hematuria, decreased urine output, signs of azotemia and unusually high levels of sulfonamide in the blood, or of any one of these manifestations treatment should certainly be discontinued.

It is obvious that the early signs of severe reactions are so occult as to be revealed usually only by laboratory studies. There is nothing unfortunately that bedside appraisal of the patient will yield in the early diagnosis of the fatal sulfonamide reaction.

BENJAMIN GOLDMAN, M.D.

Lyons, C. The Re-Evaluation of Sulfu Drugs. *M.D. Surgeon* 1944, 95 301

The toxic reactions from sulfonamides have complicated but have not seriously limited treatment. It is unlikely that new sulfonamides will be more bacteriostatic than the presently available drugs but less toxic compounds may be anticipated.

Prophylactic therapy has prevented invasive systemic infection and minimized the spread of local infections. This success suggests the oral or parenteral route as a method of choice.

Good clinical evidence for or against the continued local use of sulfonamide preparations in wounds is not available. Rapid absorption after intraperitoneal application makes it difficult to evaluate the abdominal cases in terms of local therapy. Considerable doubt prevails about the value of sulfonamides in the prophylaxis of gas gangrene. A distinct trend away from local sulfonamide therapy exists but individual preference and opinion continue to guide such practice.

General hospitals in this country are receiving casualties with chronic infections associated with retained sequestra or foreign bodies. These infections are sulfa resistant and many of the patients are sulfa-sensitive. The associated debilitated state

contraindicates intensive sulfa therapy. Such cases are more often surgical failures than sulfonamide failures but they represent a group of infections requiring some form of antibacterial therapy other than that with sulfonamides. The need for continued study of surgical infections is evident.

JOSEPH GASTER, M.D.

Bigger, J. W.: The Treatment of Staphylococcal Infections with Penicillin by Intermittent Sterilization. *Lancet* Lond. 1944, 247 497

Experimental evidence is presented to show that penicillin, although bactericidal failed to sterilize completely broth cultures of the staphylococcus pyogenes. This can be accounted for on the basis of a constant proportion of cocci which are insensitive to penicillin. The latter are characterized as persisters because of a temporary resistance to penicillin while they are in a dormant nondividing phase. However dormancy lasts for a few days and with resumption of bacterial division the organisms again become susceptible to the action of penicillin and are destroyed by it.

Clinical evidence also suggests that the same process takes place in vivo. In cases of staphylococcal osteomyelitis treated with penicillin there may be a return of activity of the disease after treatment is stopped. This may be accounted for on the basis of the survival of persisters in the infective focus which begin to multiply after the bacteriostatic action of penicillin is stopped. Polymorphonuclear leucocytes can destroy such persister cocci only slowly.

A fractional or intermittent method of sterilization is recommended to destroy all the bacteria over a period of nineteen days. This method provides for the maintenance of $\frac{1}{4}$ to 1 unit of penicillin per cubic centimeter of the patient's serum and requires 400,000 units of penicillin per twenty four hour treatment period. The plan provides for a first treatment period of four days, followed by an intermission of one day and four other treatment periods each of two days with intermission periods of one day.

In order to obtain a prompt high concentration of penicillin an intramuscular injection of 30,000 units should be given initially together with a daily continuous intramuscular drip of 100 cc. of saline solution containing 400,000 units. This method of therapy does not preclude the surgical evacuation of collections of pus which serve as reservoirs of persisters. The author also suggests that the findings described are applicable to penicillin-sensitive non hemolytic streptococci. B. G. P. SHATTUCK, M.D.

Coleman, R. and Sako, W.: The Treatment of Multiple Furunculosis with Penicillin. *J. Am. M. Ass.* 1944, 126 427

The incidence of furunculosis superimposed upon millaria is much increased during the warm summer weather. In the South this condition constitutes a common problem which often proves to be very

refractory to treatment. A remarkably rapid response of multiple furunculosis to intramuscular penicillin therapy has been observed in 6 young children. Histories of the 6 cases are reported.

SAMUEL KAHN, M.D.

McKissock, W. Logue, V., and Bartholomew, I.: The Need for Asapels in Local Penicillin Therapy. *Brit. M. J.* 1944, 55

A study of the Preliminary Report to the War Office and Medical Research Council on Penicillin by Florey and Cairns in 1943 reveals that Gram-negative organisms have been found in the discharge from penicillin-treated wounds. In some cases such organisms as the bacterium coli, proteus vulgaris and pseudomonas pyocyanus have been grown from the aspirate from wounds receiving local injections of penicillin solution, and in others they have been cultured from pus issuing from similar wounds before healing was complete. Often enough the presence of such organisms either in aspirated fluid or in purulent discharge, appeared to cause no serious complication or to delay healing unduly. The bacteriological results usually showed that after two days of treatment of the brain cavity with penicillin Gram positive cocci were no longer found in the fluid sucked or discharged from the wound but organisms of the coliform group were almost invariably present. In wounds which remained completely closed this state of affairs persisted until healing was complete. Such Gram negative organisms are present in the wound initially but are overgrown by staphylococci and streptococci in first cultures. Their presence is but another example of added hospital or cross-infection of wounds.

The opportunity for cross-infection of a wound undergoing treatment with penicillin solution is particularly good. A rubber tube runs from the outside air to the depths of the wound and through this channel injections of the penicillin solution are made usually twice daily for a period of from three to five days.

Three main points may be responsible for the very low rate of hospital or cross-infection of wounds: (1) the care taken in closing scalp wounds to obtain very early healing; (2) the insistence upon very careful ward and dressing technique; and (3) an aseptic cap used to close the penicillin tube.

The incidence of potential cross-infection was 3 cases among 30 in the unit's original surroundings, but no clinical cross-infection occurred. In a second series under less perfect conditions the potential rate rose to 7 cases among 30 (35 per cent) and 1 superficial case of clinical hospital infection resulted (5 per cent).

HARRY W. FINE, M.D.

Griep, L. H.: Allergy to Penicillin. *J. Am. M. Ass.* 1944, 126 439.

A case of penicillin allergy manifested by generalized severe urticaria and studied from the point of view of the possible immunology involved, is reported.

This allergy in all probability is not unlike that of serum allergy. As is the case in other instances of sensitization to biological products, such as insulin, the posterior lobe of the pituitary gland and liver extract the reaction occurred after the resumption of treatment following a period without treatment.

There seems to be evidence of the presence of some immune substances in the serum of the patient, such as reagins and precipitins. This is proved by the positive direct skin test, by the positive passive transfer and the positive precipitin test. What role if any these antibodies might have in mediating the reaction is not exactly clear.

The allergy to penicillin is probably unrelated to sensitivity to penicillium spores.

SAMUEL KAHN, M.D.

Bloomfield, A. L., Kirby, W. M., and Armstrong, C. D.: A Study of "Penicillin Failures." *J. Am. M. Ass.* 1944, 126 685.

From an intensive study of more than 100 patients treated with penicillin a good deal has been learned about what might be called "penicillin failures" and it is with this phase of the subject that the present article is concerned. Penicillin failures may be discussed under the following headings:

- 1 Causes of death in penicillin treated patients
- 2 Failures due to inadequate amounts of penicillin.
- 3 Failures due to inadequate surgical drainage in penicillin-treated cases
- 4 Failures due to overwhelming infection even when penicillin dosage was presumably adequate.
- 5 Failure to prevent or cure renal lesions in penicillin treated cases of streptococcal infection.
- 6 Conditions in which penicillin either fails or is likely to be inadequate.

1 Causes of death in penicillin-treated cases. Aside from patients not seriously ill, 87 instances of severe infection, including endocarditis, meningitis, and acute osteomyelitis have been treated. Of this series 7 or 8 per cent terminated fatally. It appears that only 2 deaths or 2.3 per cent, of the whole series could be ascribed to the actual failure of penicillin treatment. Ten years ago one would have had a mortality of at least 50 per cent.

2 Failures due to insufficient penicillin therapy. Excellent results have been reported with relatively small quantities of the material but this does not rule out the need of larger doses in some cases. At any rate the unsatisfactory results in the reported series seemed to be ascribable to too small amounts of penicillin or to treatment of too brief duration.

It seems clear that with any serious infection it may be well to continue treatment for several days after the process has been controlled as a possible insurance against recurrence. This applies especially to staphylococcal and streptococcal infections. In subacute bacterial endocarditis due to the streptococcus viridans the good results which are obtained in a consecutive series of 9 cases seemed to be due to the continuation of uninterrupted treat-

ment over a period of from six to eight weeks. Recurrences of acute hemolytic streptococcal throat infections common with brief treatment can be prevented by giving penicillin over a period of from five to ten days.

An analysis of 8 cases of acute osteomyelitis of the long bones in which no operation was done indicates that very intensive and prolonged therapy is necessary if serious changes are to be prevented. Even then, the roentgenograms from the second week on usually show some absorption of the cortex with periosteal reaction, possibly due to injury which began before penicillin therapy was started. Some staphylococci must be sealed in and be difficult to reach in areas made relatively avascular by thrombosis and necrosis. Prolonged uninterrupted treatment is clearly indicated in acute osteomyelitis.

3. Failures associated with penicillin therapy when adequate surgical drainage of infections was not carried out. In spite of the great efficacy of penicillin in controlling certain types of infection the principle that evacuation of closed collections of pus is necessary for rapid cure still holds good in most cases. Simple aspiration of pneumococcal empyema and of gonococcal joints with the injection of penicillin, has been adequate in many cases but in other infections especially those due to staphylococci and nonhemolytic streptococci progress may be arrested until surgical drainage has been instituted.

4. Failures due to overwhelming infection. One patient provided the only example of failure of penicillin due simply to an overwhelming infection with an organism sensitive *in vitro*. She received large doses of penicillin by continuous intravenous drip sufficient to raise the blood content to well over the standard bacteriostatic level of 0.15 unit per cubic centimeter. In spite of this the blood stream was not cleared and after twenty hours culture still yielded 130 colonies of staphylococcus aureus per cubic centimeter. The importance of using penicillinase is also brought out, as there was enough penicillin in the blood to inhibit growth in a blood culture made without penicillinase.

5. Failure to prevent or cure the development of glomerular nephritis in certain patients with streptococcal infections treated with penicillin. The association of glomerulonephritis with certain types of streptococcal infection is clearly established. When penicillin became available it seemed of particular importance to find out if this agent which estimates so many streptococcal infections with great speed would prevent the occurrence of nephritis. Of no less interest was the question of whether nephritis already established would clear up after the elimination of concomitant streptococcal infection by penicillin, as for example in bacterial endocarditis.

There is no evidence that the course of nephritis is influenced, but every reason to believe that when an irreversible lesion has been set up it will progress in the usual relentless fashion of chronic glomerulo-

nephritis. Similar observations by one of the authors (C.D.A.) in cases of bacterial endocarditis due to the streptococcus viridans have shown that the renal lesion may persist after the infection has been eliminated. All this is in harmony with the evidence accumulated by Addis to the effect that glomerular nephritis once under way tends to propagate itself.

6. Conditions in which penicillin either fails or is likely to be inadequate.

Pneumococcal meningitis.—Although pneumococci are often highly sensitive to penicillin the results of treatment of pneumococcal meningitis have been unsatisfactory in many ways. These poor results are doubtless attributable in some degree to the nature of this infection with its well known tendency toward adhesive arachnoiditis, encephalitis and thick gelatinous exudate which impedes the local application of any therapeutic agent. Since sulfonamides are quite effective in pneumococcal meningitis it may turn out that sulfonamides together with penicillin may be the best treatment.

Chronic (staphylococcal) osteomyelitis.—In contrast to the results in acute staphylococcal osteomyelitis the results in most of the chronic cases have been unsatisfactory. If the lesion is in a long bone and can be laid wide open by surgical means, local penicillin irrigations seem to aid in rapid healing. In cases with sinuses leading into the pelvic bones or into the spine (inaccessible to surgery) neither local irrigations nor heavy intramuscular injections have had any definite effect.

7. Conditions in which penicillin was entirely ineffective

Tuberculous paravertebral abscess (no effect)

Lymphoid leucemia (no effect)

Aleukemic myeloid leucemia (no effect)

Infectious mononucleosis (no effect) (This condition developed in a patient with acute osteomyelitis while under active penicillin treatment.)

Mycosis fungoides (no effect)

Chronic (rheumatoid) arthritis (no effect)

Filariasis (no effect) (The blood count of the microfilariae remained unchanged during the penicillin administration.)

8. Relation of penicillin failure to the sensitivity of strains *in vitro*. Even within categories of bacteria such as streptococci and staphylococci and others which are in general sensitive to penicillin there may be strains which are resistant *in vitro*. It is evident that failure of therapy in an individual case may be due to strain resistance and the need of *in vitro* tests in routine work is emphasized.

ANESTHESIA

Arrowood, J. G., and Foldes, F. F.: Subarachnoid Analgesia Maintained by the Continuous Drop Method. *Arch. Surg.* 1944 49 241.

The authors describe a technique for the continuous drop method for maintaining subarachnoid

Fig. Diagram of apparatus

analgesia. The equipment consists of a 250 cc leveling flask and tube set with a Murphy dropper

a regulating valve and a glass adapter. The initial dose of anesthesia is given in the same manner as would be used with the fractional method of administration.

The apparatus is then hooked up to the malleable spinal needle. Analgesia is maintained by the drop method. The leveling flask containing 0.5 per cent procaine hydrochloride solution is suspended from 60 to 80 cm. above the level of the spinal needle. About twenty minutes after the initial dose approximately 40 drops of 0.5 procaine solution are permitted to run in. The valve is then carefully regulated so as to deliver the desired number of drops which may vary from 4 drops per minute on up.

Twenty-seven consecutive cases are summarized in table form with details as to the dosage given, the adjuvant anesthesia, and the duration of the operation.

It is believed that this more sensitive method of giving continuous spinal anesthesia will maintain the necessary level of analgesia from moment to moment and will keep the concentration of the drug in the spinal fluid at a minimum at all times. It also provides a perfectly aseptic technique for once connected the system can be kept completely closed at all times.

The safety of the technique depends on its meticulous application and upon expert observation and management of the patient. It is advised therefore that it be used only by the experienced spinal anesthetist who can give it his undivided attention.

MARY KARP M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Wyatt, G. M., and Spurling, R. G. Pantopaque. *Surgery* 1944, 16 561

Pantopaque is the contrast medium of choice for myelography. It is preferable to lipiodol in that it is more readily absorbed and does not remain in the subarachnoid space as a persistent foreign substance. Also, it is nontoxic more fluid than viscous (therefore, it fills out the smaller dural nerve sheaths) more easily removed and it is no more irritating than lipiodol. The sharp roentgenographic contrast which it affords renders it superior to the gases.

The authors were impressed with the rapid absorption of pantopaque which is its chief advantage. Six patients from whom pantopaque was incompletely removed were studied. The entire spine and skull were observed roentgenologically at time intervals varying from one to fifteen months. Absorption was more rapid during the first few months and was retarded over the remaining period eventually absorption was almost complete.

It is believed that the variability in the rate of absorption may be due to the nature of the contrast medium, which is a mixture of isomers. Another factor in favor of rapid absorption is the emulsifying action of body motion on larger collections (0.5 cc) of pantopaque. The medium produces a tissue reaction similar to that of lipiodol when observed after a few months the material was fixed in position. However none of the patients complained of symptoms that could be referred to the residual pantopaque.

MAURICE D. SACHS, M.D.

Hodson, C. J.: Four Primary Roentgenological Lesions Found In Traumatic Chest Cases. A Preliminary Report. *Brit J Radiol* 1944 7 296

Two hundred and fifty thoracic casualties received from within one to twenty-one days after wounding were examined in a thoracic unit in the Mediterranean theater of war.

In 12 cases radiopaque linear shadows were found traversing the lung along the path of the missile. In the early stages, whatever the shape of the lesions they present hazy and ill-defined margins and are often so faint as to be barely visible on the film. In time there is a characteristic change in appearance and at the end of two or three weeks these lesions show plainly as clear-cut linear oval, or rounded shadows from 0.5 to 1.5 cm. in length leading across the lung field to a foreign body or a secondarily damaged rib at the other end. Coincident with this greater clarity of definition is an increase in the density of the shadows. The course is typical over a period of weeks. The lesions slowly become narrower and more opaque until they are lost to sight. When viewed at right angles these tracks show as

definite bands along the course of the missile but when seen end-on or obliquely they become fore-shortened and appear as small oval or rounded shadows suggestive of hematomas or abscesses of the lung. These lesions are similar in nature to missile tracks in other tissue. Postmortem examination in 1 such case showed the lung tissue to be torn along the path of the missile with hemorrhage into the space so formed. Around this central core of blood was a more widely spread area of solid lung due to ecchymosis and edema of the parenchyma which merged gradually into normal tissue. Presumably as the lesion heals the ecchymosis and edema are absorbed and this more solid central core is left to organize which results in a tough fibrous band firmly attached to surrounding structures. One practical point of value of these tracks is that (in 3 cases) they have led to the discovery of foreign bodies otherwise invisible behind the heart or under an effusion.

In 6 cases a different variety of track was observed. Associated in every case with an entry wound and bone damage at one end and a foreign body or exit wound at the other were found 2 roughly parallel linear shadows traversing the lung. In the 3 cases in which these could be viewed end-on an air-containing hole was seen. The presence of varying fluid levels in 4 of these cases and the marked resemblance of a tuberculous cavity in 1 suggested that air-containing missile tracks were present.

In length they vary from 4 to 10 cm. in width from 0.2 to 2 cm. Their walls may appear to be from 2 to 3 mm. thick or practically invisible; their caliber varies slightly along their course but on the whole they are digitate rather than fusiform. They tend to end abruptly about 1 or 2 cm. from the parietes or the foreign body. When viewed end-on they may appear rounded or oval and may resemble a tuberculous cavity or small lung abscesses. These cavities slowly heal by closing up from side to side over a period of weeks. The period during which they were under observation varied from eighteen to thirty-six days. There was no characteristic symptomatology. The significance of these lesions appears to be chiefly in the problem of their recognition and their differential diagnosis from a tuberculous lesion.

Extrapleural hematomas have been found around rib fractures, and in cases in which foreign bodies have come to rest in or just inside of the plane of the ribs. They consist of blood which has collected between the intercostal muscles on the one hand, and the parietal pleura on the other stripping of the pleura from the parietes results with its indentation into the lung parenchyma as the covering to a rounded hematoma. At operation the pleura has been found to be firmly adherent to the chest wall at the periphery of the lesion.

The roentgenological appearance is of a rather dense rounded shadow arising from the chest wall. It may arise gradually or steeply at its edges, and sometimes it overhangs at its lower border giving almost a pedunculated appearance. When viewed at right angles to the plane of its base it often has, especially when a week or two old a sharply defined border resembling a cyst. In size these lesions vary from 2 or 3 to 10 or 15 cm. in diameter. A lesion projected 7 cm. into the lung substance. They may occur anywhere over the chest wall but are usually visible only in the upper chest. In 4 cases there were four or more fluid levels and in 2 cases there were also small intrapleural effusions on the same side. The contents of these lesions may be fluid, clotted or infected blood and the gas they contain arises presumably from contact with the exterior or from gas-forming organisms. In 4 of the cases at operation a foreign body was found to be lying within the lesion's limits, with or without bone fragments from rib damage. These lesions slowly resolve over a period of weeks gradually subsiding to the chest wall, until they appear only as thickened pleura. The duration of this process is from four to eight weeks according to the size of the lesion. Such a process may become infected and if this occurs the area can be drained without involving the pleural cavity and the danger of empyema is thus avoided.

Lung contusion is a name given tentatively to the diffuse shadow found in so many traumatic chest cases when there is no evidence of pleural effusion to account for this change in density. It occurs in almost any type of lesion but is most striking in cases of chest wall injury when penetration of the pleura or parenchyma does not appear to have occurred. It may be associated with severe blows on the chest and with close up explosions, such as the detonation of cartridges carried in the patient's clothing without penetrating injury.

The etiology of this condition would appear to be similar to a blast effect. An early clouded appearance of the lung parenchyma is produced, which clears in the course of a few days occasionally the condition resembles an inflammation due to pleural effusion.

HAROLD C. OGDEN, M.D.

Rackow, A. M.: Some Problems of Appendix Radiology. *Brit. J. Radiol.* 944, 7 265

Roentgenography of the appendix is usually either neglected or abused. Although frequently the radiologist is called upon to render an opinion pertaining to the appendix actually little has been written concerning the roentgenographic appearance of the normal appendix.

The appendix can be visualized by a follow-through barium meal or barium enema, most authorities prefer the former. The mode of filling the appendix is passive but emptying is accomplished by contraction. In the past too much importance has been placed on the nonemptying of the appendix within twenty-four hours. Appendical barium retention may be caused by dehydration and caking of

the barium which produce concretions that are gradually expelled. A nonfilling appendix need not be due to pathology. It may be that during the examination period no barium was present nor had been expelled.

The author has adopted the following routine.

In the morning, a follow-through barium meal is given. From two to three hours later the patient is given 2 drachms of magnesium sulfate. The cathartic seems to stimulate appendiceal activity. Twelve hours later a second follow-through barium meal is given. It is probable that the second dose of barium will remain somewhat longer in the cecum after the effects of the magnesium sulfate have worn off and thus an opaque filling of the relaxed appendix will be provided. This method was successful in 76 per cent of the cases in which it was tried (25 of 33) as compared to success with one barium meal in 41 per cent (16 of 39).

The form and position of the appendix vary and the width of the lumen is variable. An indication of pathology is irregularity rather than total width. Segmentation may be due to local constrictions or to subdivisions of the barium caused by fecal particles. Neither is pathological. However if local constriction is constant it should be regarded with suspicion. A curled appendix may be due to a short meso-appendix. If the tip of the appendix is adherent to the iliopsoas muscle, pull on the cecum stretches the appendix and causes pain. Local tenderness may be deceiving because some physicians have an unconscious tendency to use more pressure when palpating over McBurney's point.

The author thinks that more attention should be paid by radiologists to appendiceal pathology. One way of learning more in this field could be realized by examining a series and establishing a normal criterion.

MAURICE D. SACKS, M.D.

Copleman, B.: The Roentgenographic Diagnosis of the Small Central Protruded Intervertebral Discs Including a Discussion of the Use of Pantopaque as a Myelographic Medium. *J. M. J. Radiol.* 944, 53 245.

The practice of the Neurosurgical Section of the Army Hospital with which the author is affiliated has been to request a myelographic examination in every case of suspected protruded intervertebral disc in which the lesion has been incident to Army service. As a result 150 cases were examined by means of myelography in slightly more than a year 86 of which were operated upon.

The many advantages of myelography are well known. In the author's series, however there are 5 cases in which very small midline protrusions of the intervertebral discs were detected by a most careful application of such a procedure and therefore their publication appears worth while.

The general technique of procedure is as follows.

The patient is placed in the lateral recumbent position as usually applied for lumbar puncture, on a roentgenographic-roentgenoscopic tilt table and,

after local anesthesia with novocain solution a lumbar puncture needle is inserted into the third or occasionally the second lumbar interspace. When a free flow of spinal fluid is obtained 3 cc of pantopaque are injected firmly and steadily so as to obtain a solid column of opaque medium. The stylet of the needle is then replaced and the patient turned slowly on his stomach. The table is now tilted and the advancing margin of the opaque column is watched for deformities until the third lumbar interspace is bridged. If slight persisting deformities are observed "spot" roentgenograms are made. The table is tilted still further and the fourth and fifth lumbosacral discs and the cul-de-sac are investigated roentgenoscopically and by spot roentgenograms. The column is then allowed to ascend the lumbar spine and additional careful studies are made. Finally the patient is turned into the prone position, the opaque column is maneuvered (by tilting the table) beneath the needle, and the opaque medium is withdrawn.

As a rule only the last three interspaces are examined but when the clinical examination indicates the upper segments of the spine are also investigated. The roentgenograms are made with the roentgenoscopic tube and a spot film device usually in the anteroposterior and moderately oblique views.

By following this procedure the author was able to discover in the 5 cases mentioned very small central disc protrusions whereas otherwise the condition might have been missed. It is important that in such cases the edge of the opaque column be allowed to advance slowly and gradually so that the outline of small protrusions be visualized before the bulk of the opaque substance obscures it. The 5 cases are briefly reviewed and their instructive roentgenograms reproduced. In all of the cases there was considerable pain which was completely relieved after removal of the protruding discs.

The author is of the opinion that the roentgen demonstration of these lesions was greatly facilitated by the use of pantopaque, a new opaque myelographic medium introduced during the past two years. The advantages of pantopaque are several. It is a freely flowing oily substance with less tendency to break up into globules than lipiodol. It casts an excellent shadow but does not obscure fine gradations of density and above all it is nontoxic. In all but 1 of the patients in whom the opaque material has been allowed to remain no ill effects of any kind were observed. The author cannot attest to the absorptibility of the drug since his longest observations started only six months ago but it is said that pantopaque absorbs slowly (about 1 cc. a year).

T. LEUCUTA, M.D.

Gianturco, C.: A Roentgen Analysis of the Motion of the Lower Lumbar Vertebrae in Normal Individuals and in Patients with Low Back Pain. *Am. J. Roentg.* 1944, 52: 261.

The normal movements of the spine are connected with several factors including muscular pull load upon the discs, intranuclear pressure and the condi-

tion of the articular facets. These factors vary with various segments of the spine and are altered by certain pathological conditions. It occurred to the author a little over a year ago that some advantage may be derived from a roentgen study of the pattern of motion of the various vertebral segments. With this view in mind he devised a method which permits such a study.

The method consists in the taking of 3 roentgenograms of the lumbosacral spine in the lateral position, one with the spine at rest, one with the spine in flexion and one with the spine in extension. The patient is placed in a special seat constructed by the author so that the pelvis is immobilized during the actual process of roentgenography. By superimposition of the sacrum in the 3 roentgenograms the shadows of the lower border of the fifth lumbar vertebra cross each in a definite manner. With the aid of an illuminator and sharp pointed pencil straight lines are drawn tangential to the lower contour of the fifth lumbar vertebra marking these shadows. The point of intersection of the line in straight erect position and the line in flexion represents the fulcrum of flexion of the fifth lumbar vertebra and the point of intersection of the line in straight erect position and the line in extension represents the fulcrum of extension of the fifth lumbar vertebra. The same procedure may be applied to the lines of the fourth and third lumbar vertebrae. So far no attempt has been made to extend the examination to segments above the third lumbar vertebra since a rather complicated device would be necessary for the taking of the roentgenograms above that level.

Obviously the terms fulcrum of flexion and fulcrum of extension although descriptive are not very accurate. The flat surface of the vertebral body as it slides over the turgid nuclear substance produces many intermediate points of crossing if roentgenograms in other degrees of flexion or extension are made. The points mentioned represent the two opposite extremes.

The author first applied the method to 20 normal individuals between the ages of nineteen and thirty-five years. In these with a normal pattern of motion the fulcrum of flexion and extension of the third, fourth and fifth lumbar discs were found to lie within very narrow limits at about the center of the nuclei. The average distance between the fulcrum was 5 mm with a minimum of 3 mm and a maximum of 8 mm. The fulcrum of flexion was always anterior to the fulcrum of extension.

Then he studied 35 patients with low back pain. Twenty of these patients showed normal pattern of motion but in 15 there was deviation from the normal. The exact distribution of the lesions in all cases is shown in Table I.

In attempting to explain abnormal vertebral motion the author discusses the importance of the muscular action, the effect of the bony lesions, the behavior of the posterior articulations of the spine and the influence of limited changes involving the

TABLE I — DISTRIBUTION OF LESIONS

Normal motion 30 cases (54%) without bone lesions, 6 cases, with bone lesions, 4 cases.		Abnormal motion 5 cases (46%) without bone lesions, 9 cases with bone lesions, 7 cases.	
Bone lesions found		Bone lesions found	
Cases		Cases	
Spondylolisthesis, grade		Spondylolisthesis, grade	1
Hypertrophic changes		Hypertrophic changes	1
Schmorl's nodes	1	Osteochondritis juvenilis	
		Old compression fracture	
		Unilateral sacralization of the fifth lumbar	

intervertebral discs. It is fully realized that a great deal of investigation will be necessary to establish the exact anatomical basis for the various types of abnormal motion.

The fact that in a high percentage of patients with low back pain abnormal vertebral motion was found is significant. It is hoped that this will stimulate further research.

T LUCOTIA, M.D.

Rhodes, A. W. and Borrelli, F. J.: Giant Hemangio-endothelioma with Thrombocytopenic Purpura. *Am J Roentg* 944, 52-53.

Giant hemangioendothelioma with thrombocytopenic purpura is a rare entity. The literature reveals the report of only one other case.

In the present case, a tumor of the back and neck was noted at birth (November, 1941) and diagnosed as lipoma. Two months later it began to increase in size with a blue discoloration. The tumor blanched on pressure. Petechiae and small areas of ecchymosis were present throughout the body. The tumor continued to increase in size and the patient was admitted to the hospital, vitamin K and multiple transfusions were given. In addition 220 roentgens were given in one dose with 150 kv and 1 mm. of aluminum filter at 25 cm. distance with no effect. The mass continued to increase in size and extended to the left side of the face and chin involving the entire left thoracic wall. Hemorrhagic spots were noted around the base of the tongue, soft palate, fauces, and pharynx. The spleen was palpable. The hemoglobin was 9.2 gm. the red blood cells numbered 3 million, the white blood cells 15,500 and the platelets 15,000 the coagulation time was four minutes and the bleeding time twenty five minutes. Roentgenograms revealed a soft tissue tumor of the chest and neck but no evidence of bone destruction.

On May 4, the patient became critically ill following an upper respiratory infection. Two courses of radiation therapy were given. The first course was given over a period of three weeks (from May 8 to June 1) and consisted of 10 treatments, 100 roentgens per treatment, 4 portals, from 7 by 7 cm. to 1 by 10 cm. 140 kv, 3 mm. of aluminum filtration at 5 cm. tube-skin distance. Three hundred roentgens were given to the left lateral neck, 300 roentgens

to the left shoulder (lateral port) 300 roentgens to the left shoulder (anteroposterior port) and 300 roentgens to the left shoulder (posteroanterior port). A slight change was noted and two weeks later a second course was given 300 roentgens to each of the three ports. In August, a third course of irradiation was given 160 kv 25 cm. distance, open field inherent filtration of 0.15 mm. of copper 275 roentgens to the shoulder (posteroanterior field). The same dose was repeated two days and two weeks later with a 20 by 20 cm. field at 50 cm. distance and on October 23 275 roentgens were again given with a 20 by 10 cm. field.

Response to radiation therapy was gratifying. Within two months, the mass regressed in size and the discoloration faded slowly. Biopsy report of the lesion was hemangioendothelioma. Observation one year later revealed that most of the skin looked normal except for a slight purplish discoloration of the arm due to recent bleeding, and the shoulder skin was roughened and red. Both areas were given a single dose of 275 roentgens. The bleeding time was four and one-half minutes and the clotting time one and one-half minutes. The platelets numbered 450,000 per cubic millimeter. When last seen, the purple areas had disappeared and the child was developing normally.

The authors raise one very pertinent point concerning the efficacy of radiation therapy. The involved fields were extensive undoubtedly the irradiation of the ribs and spleen underlying the tumor helped not only in the regression of the tumor but also in the elevation of the platelet count, which resulted in a lowering of the bleeding time and disappearance of the purpura.

MAURICE D. SACKS, M.D.

Cantril, S. T., and Buschke, F.: Roentgen Therapy in Gas-Bacillus Infection. Report of 9 Cases with Recovery. *Radiology* 944, 431-433.

There appears to be considerable difference of opinion regarding the efficacy of irradiation in the treatment of gas gangrene. Opponents of this type of treatment state that animal experimentation has not been successful. Recently however Merritt described experimental gas gangrene in sheep, and it is the authors' belief that this report should answer the critics.

Nine cases of gas gangrene are reported in detail. The final results clearly demonstrate that x-ray therapy alone or in conjunction with surgery is very effective in the management of gas gangrene. (Emphasis is placed on the individuality of each case regarding surgery and irradiation.)

All 9 of these cases of gas-bacillus infection were due to trauma. Although there was no mortality in the series the authors believe that it may not always be possible to maintain so low a mortality rate. They further believe that in all probability the long-term mortality rate will be similar to that of Kelly (1.2 per cent). Without doubt, a mortality of from 10 to 15 per cent is a very marked saving in lives.

Because of the extent of the trauma amputation was necessary in 4 of the cases in 3 of the 4 cases x-ray therapy served to limit the infection and reduce toxemia and the patients became better surgical risks for amputation. In the fourth instance although the extent of trauma made immediate amputation unequivocal there was a reduction in toxemia.

Four other patients received therapeutic doses of antitoxin. One had a severe serum reaction. The authors are of the opinion that these patients would have recovered regardless of whether or not the antitoxin had been used. Sulfonamides were effectively used in 2 cases with secondary bacterial infection after the gas-bacillus infection was under control and x ray therapy had been discontinued. Chemotherapy was used in several other cases but the authors are convinced that this did not help in controlling the actual progress of the disease other than to combat secondary bacterial infection.

The authors conclude that the mortality from gas gangrene, whether in civilian or military life can be minimized by thoughtful diligent use of both surgery and roentgen ray therapy.

MISCELLANEOUS

Alexander T. C.: Irradiation Pneumonitis. Report of a Case. *Bull Johns Hopkins Hosp.* 1944 75 199.

The author reports a case of Hodgkin's disease in which the patient died from pneumonitis as a result of overirradiation of the mediastinum and unprotected lungs.

The patient was treated from January to September 1939 and he died on September 28 1939. During this period he received the following amount of radiation over the mediastinum and adjacent lungs from January 21 to March 1 a dose of 1 050 roentgens in air given in 10 fractions through a field 10 by 20 cm. over the mediastinum anteriorly and a similar dose posteriorly from April 26 to May 4 a dose of 420 roentgens in air given in 4 fractions through a field 10 by 20 cm. over the mediastinum anteriorly and a similar dose posteriorly from July 31 to August 17 a dose of 2 018 roentgens in air given in 10 fractions through a field 15 by 15 cm. over the mediastinum posteriorly and a dose of 1 818 roentgens given in 9 fractions through a field 20 by 20 cm. over the mediastinum anteriorly and, finally from September 22 to September 28 a dose of 243 roentgens in air given in 3 fractions through a field 20 by 20 cm. over the mediastinum posteriorly. Thus during eight months a total of 7,019 roentgens in air was administered to the mediastinum through fields as described without any provision for shielding the lungs. The factors employed were 200 kv p 20 ma. 50 cm. skin target distance, Thoracul filter 2 mm. of copper plus 1 mm. of aluminum.

The patient developed severe respiratory embarrassment with progressive cyanosis in the terminal stage and a roentgenogram eight days prior to his death revealed an extensive pneumonitis. Post mortem examination showed pulmonary changes which were similar to those produced by overirradiation in experimental animals by Davis and described later by McIntosh and Spitz and by Warren and Spencer. No evidence of Hodgkin's tissue was found in the lung tissues.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Ladell, W. S., Waterlow J. C. and Hudson, M. F.: Desert Climate; Physiological and Clinical Observations. *Lancet* Lond., 1944, 247, 491

Heat exhaustion of type 2 was seen almost exclusively in the second half of the summer. The incidence seems to be related not to the height of the temperature but to the duration of the hot weather. The most prominent symptom was defective sweating which was a complaint in 37 per cent of the cases. The duration of this symptom was short in some cases and as long as three weeks in others. A common symptom in this type of case was dyspnea, which was present in 23 of 55 cases, and was associated with numbness and tingling of the hands and feet in 8. Dyspnea and exhaustion were worse in the middle of the day. Often the subject felt fairly well in the early morning but symptoms began to come on at about 11 a.m. Vomiting and cramps were present in only 2 cases and were not severe. Increased frequency of urination was extremely common. Several patients said that the frequency started when sweating began to be defective. These patients did not look ill. There was slight tachycardia on admission. The pulse volume was also good. The mean systolic pressure lying down was 121 mm Hg which is nearly 20 mm. higher than the mean in controls at the same time of year. The diastolic pressure was quite variable with a mean of 69 mm. Hg. Many patients showed obvious and easily elicited capillary pulsation in the nail bed. The reaction to standing was normal. High temperatures are not found and this is one of the features that differentiates this group from hyperpyrexial cases. Eighty per cent of the patients of this type had had severe or moderately severe prickly heat and this was characteristically in the scaling stage. The outstanding chemical feature of these cases was the excretion of large volumes of dilute urine. The greatest volumes of urine were recorded toward the end of the season. The only abnormalities found in the blood were reduced whole blood chloride and reduced plasma chloride. Blood urea levels were low.

All patients were encouraged to drink larger amounts of fluid. Salt by mouth in doses of 35 to 1 ounce were given to alternate cases. Progress in objective signs was slow. The average blood pressure on discharge was identical with that on admission. The low diastolic pressure and high pulse pressure noted in some cases often persisted for many days. The urine output remained high. The average weight gain in these patients during their stay in the hospital was 41 ounces which was significantly less than the average gain of 121 ounces in those with heat exhaustion of type 1. Extra salt

by mouth did not have any effect upon the amount or rate of gain in weight.

HAROLD C. OCTAVIAN, M.D.

Ladell, W. S., Waterlow J. C. and Hudson, M. F.: Desert Climate; Physiological and Clinical Observations. *Lancet* Lond., 1944, 247, 517

An outline is made of observations in Shaiba in southern Iraq on British Army personnel during the summer of 1943. Maximum temperatures above 100 F occurred daily for four months and there were two periods, one of a week and the other of a fortnight, when the temperature each day was above 115 F. The humidity was low and the climate was thus a true desert climate. Observations were made on 24 soldiers. The pulse rate of the subjects lying down remained constant throughout the summer at an average level of 65. At the beginning of the summer, the average blood pressure taken on subjects lying down was 112/72 mm. Hg. As the weather became hotter the blood pressure gradually fell to a minimum of 97/62. Thereafter it rose again but by the end of October it had not reached the initial level found in May. All the subjects lost weight in the hot weather and some of them lost as much as 7 per cent of their initial body weight. When the weather became cooler they recovered weight. The volume of urine passed in twenty-four hours also fell as the weather got hotter. A low urine output was associated with a high blood urea. Dehydration was most probably the result of the insufficient intake of salt. It was found that those subjects who lost most weight had the greatest chloride concentration in their sweat. These observations suggest that there are certain individuals who have a higher salt requirement than the average. They react to high rates of sweating by cutting down salt loss in the urine to a minimum. The chloride content of the body fluid is kept up by a reduction in the total fluid volume shown by the loss in body weight.

Hyperpyrexia. Twelve patients were seen who had a rectal temperature of 107 F or more. Of these 12, 9 were over thirty years of age compared with 40 per cent over thirty in the whole series. Five of these cases occurred during the hottest week of the summer.

In most patients the onset was sudden. All except 1 gave a history that sweating stopped over a period varying from twenty-three days to half an hour before the attack. The main elements in the clinical findings were rectal temperature of 107 or more, a skin hot and dry to the touch all over the body and partial or complete loss of consciousness. Abdominal and tendon reflexes were absent in only 3 cases. Blood samples showed diminished hemoglobin and a chloride content in both the whole blood and the plasma which was slightly less than normal. The

blood-urea and plasma levels were within the limits found for controls. The sodium content estimated on 2 samples only was also normal. Although there was some chloride deficiency in the blood there was an apparent anomaly in that all these cases had chloride in the urine. Treatment was along established lines. The body temperature was reduced with wet sheets and fanning of the patients who were then transferred to an air-conditioned ward with a temperature of about 80° F. Losses from rapid sweating were restored within twelve hours of the onset in most cases.

The laboratory findings fit in with the theory that the first breakdown is in the sweating mechanism. Recovery was rapid and uneventful.

Heat exhaustion type 1. The great majority of this type of cases were seen in the two hottest weeks of the summer. The history was usually short, from two to four days. Complaints of dizziness, anorexia, headache, and constipation were present in varying combinations. Vomiting and cramps were prominent symptoms, cramps usually preceded the vomiting. Most of these cases had no history of diminished sweating or of increased frequency of urination. On admission the patients looked exhausted, anxious and ill. They were pale and sweating profusely with a cool skin. They showed the classical signs of dehydration.

The average rectal temperature was 100.6° F. The average pulse rate on admission was 90 in 35 per cent the pulse volume was poor. In patients lying down, the systolic pressure was occasionally low but the diastolic pressure in most cases was higher than in the controls.

In the first twenty four hours after admission the patients passed relatively little urine and this was heavily pigmented; the specific gravity was often over 1.020. Intravenous administration of saline solution and fluids given by mouth increased the urine volumes. A raised hemoglobin and plasma protein content indicated hemoconcentration. The chloride content of the whole blood and that of the plasma were both grossly diminished; the drop in chloride of the whole blood was more marked than that in chloride of the plasma. The blood urea was raised in all cases.

In all cases liberal fluids by mouth were ordered. Some patients were given extra salt by mouth in daily doses of 1 ounce. Those who were dehydrated or could not retain fluids received intravenous saline solution usually from 4 to 5 pints in three hours. Most of the patients responded rapidly to treatment.

The evidence points to a salt deficiency dehydration as the cause of type 1 heat exhaustion. This develops when sweating rates are high in individuals who habitually excrete an unusually high concentration of chloride in their sweat. It can be prevented by drinking enough to keep the urine output at least at 30 ounces a day and by the administration of 48 gm. of sodium chloride daily. The personnel should be weighed at regular intervals during the hot

weather and any man who shows a persistent loss of body weight should be instructed to drink more water and take more salt.

HAROLD C. OCHSNER, M.D.

Elkinton J. R. and Winkler A. W. Physiological Effects of Drinking Undiluted Sea Water. *War Med. Chir.* 1944, 6: 241.

Recent clinical and experimental observations indicating the cause of the deleterious effects of drinking undiluted sea water are presented. In composition sea water closely resembles vertebrate extracellular fluid except that its total ionic concentration is about four times as great. In view of the fact that indefinitely large amounts of sea water can be ingested if sufficiently diluted with fresh water, it would appear that the deleterious effects of drinking undiluted sea water are related to its hypertonicity. Since the highest recorded concentration of sodium as sodium chloride in human urine does not exceed 19 per cent the ingestion of undiluted sea water presents a dilemma to the organism. Either some of the ingested sodium chloride must fail of excretion or body water must be sacrificed to eliminate the salt. Magnesium and sulfate require even more water per mol for their excretion than sodium chloride since the former ions are excreted in isotonic concentration by the intestine.

The actual response of the organism to drinking undiluted sea water will depend on many factors including the state of hydration of the body and the rate of ingestion of the sea water. In any event hypertonicity of the body fluids must result. The character of the hypertonicity however depends on whether or not salt is retained. With no retention of sodium chloride, loss of fluid is distributed over both extracellular and intracellular compartments in proportion to their initial magnitudes. On the other hand any retained sodium or chloride is confined to the extracellular phase of the tissues with a resultant osmotic shift of water from the cells to the extracellular fluid.

Experiments done on human subjects are necessarily confined to the early stages of the effects of ingestion of hypertonic saline solution. The later and more severe physiological effects were studied in dogs. Both acute and chronic experiments were included. Since dogs can produce urine that is more concentrated than that of human beings it was necessary to give the dogs a 5 per cent saline solution as compared to a 3.5 per cent solution for human beings in order to produce an analogous condition. The experiments illustrate clearly an important difference between the earlier and later distribution of the dehydration which results from the persistent ingestion of hypertonic saline solution. Complete excretion of salt may be attained at first with presumably the same proportion of depletion for both the extracellular and intracellular phases. As dehydration progresses body water is not so readily sacrificed and some sodium chloride is retained which results in excessive depletion of the intracellular fluid.

to maintain the extracellular concentration. The extracellular volume was fairly well maintained in spite of progressive total dehydration. The urinary concentration of salt gradually rose but did not reach the level of the concentration of salt in the solution ingested. Shortly before their death the animals exhibited various disturbances of the central nervous system including tremors, hyperactive reflexes, motor inco-ordination, and finally irregular and falling respiration. The circulation in the meanwhile continued to function well. There was no collapse of the plasma volume, renal excretion remained active, the pulse was vigorous and the electrocardiograms were normal. The terminal event was respiratory failure and the picture was clearly not one of circulatory failure.

From a practical standpoint there would appear to be no advantage to castaways in the drinking of diluted sea water instead of ingesting the diluent alone. With respect to the suggestion that water requirements might be met, as in seals, by the ingestion of fluids from the flesh of fish, the authors state that this is reasonable from the standpoint of salt excretion, but it ignores the fact that much urea, requiring water for its excretion, is formed from the protein which is in the fish.

JOHN L. LINQUIST, M.D.

Altman, R.: The Prophylaxis of Cutaneous Cancer. *Edinburgh M J* 1944, 5: 339.

Cancer is a disease which is increasing in importance in view of the amount of attention which has been directed to it and the misery and suffering which it brings so often in its train. It has frequently been asserted that the incidence of cancer is greater than formerly. This view however has been questioned those who oppose it maintaining that the increase is to a large extent due to the fact that it is readily recognized now whereas formerly it escaped observation. It is interesting in this connection to study the figures of cancer as seen in the Skin Department of the Royal Infirmary in relation to the number of out-patients attending.

These figures show that the percentage increase of cancer of the skin in recent years is negligible. There has been rather more than a 40 per cent increase in the number of new patients attending the Skin Department during the last ten years while the increase in the cases of skin cancer has been 0.11 per cent.

One point has to be kept in mind in studying these figures. In the author's opinion more cases of rodent ulcer at an early stage are being sent up to the Skin Department than formerly. It being not uncommon now for rodents the size of a lentil or less to be referred for treatment.

Another point to be noted is the small number of cases of squamous-cell cancer. An average of just over 3 per annum has been seen against an average of 90 rodents. Thus the squamous-cell carcinoma forms a very small percentage of the total cancer cases.

It might be thought that the skin is an excellent organ for studying the problem of cancer and in some respects this is true. We are however faced with the difficulty that we know so little of the cause of cancer of the skin. It is true that certain substances are prone to produce cancer but that does not take us far. These carcinogenic substances, as they are called, produce only one type of cancer and that is the less common squamous-cell variety. No such substances can be blamed for producing the rodent ulcer type which, as is seen from the figures given, is much the more common. About the cause of this type we must confess ignorance, and so no prophylactic measures can be taken. The relationship of injury to cancer is not clear. This is true of cancer of the skin as well as of cancer of other organs. It is unusual to obtain any history of injury in cases of rodent ulcer.

The substances which produce cancer are many and varied. Most of these are external irritants but there is one drug which when taken internally over a prolonged period, tends to give rise to squamous epithelioma. This drug is arsenic. Prolonged ingestion of arsenic gives rise to hyperkeratosis of the palms and soles, and eventually some of these hyperkeratotic areas become malignant.

Many physical and chemical agents produce cancer of the skin. The most notable are light, heat, and x rays among the physical and soot, tar, pitch, anthracene and paraffin among the chemical. It is probable that a particular type of skin, inherited or acquired, is necessary for the development of cancer as it is only a small proportion of persons coming in contact with these substances who develop the cancerous condition.

Most of the other substances which ordinarily produce carcinoma are met with in the course of working with them, the condition thus becoming an occupational hazard. Soot is known to be provocative of cancer and it was the first product of coal distillation known to produce injury. Potts described chimney-sweepers' cancer which occurs on the scrotum and it is curious that this form of the disease seems to occur according to Pusey only in England.

Tar and pitch are other substances which produce skin cancer. According to Prosser White, lignite, gas-works tar, producer gas tar and coke-oven tar will give rise to epithelioma, while blast-furnace tar does not either in men or mice. It would seem that it is the fractions which distill at a high temperature which cause epithelioma, and the critical temperature seems to be about 350° C. In the Skin Department many patients are treated each year with crude coal tar and there has not been a case recorded in which the patient developed cancer as the result. Not one of the cases of squamous-cell carcinoma occurring in the ten year period mentioned earlier had had any tar treatment, nor so far as the author is aware has any of the numerous patients who received treatment with crude-coal tar ever developed carcinoma of the skin as a result.

Another industry in which cancer has been common is the cotton industry. Here the mule spinners are those chiefly affected. It may occur on the arms but the scrotum is the place usually associated with epithelioma in this industry. The oil from the spindles is thrown out as they rapidly rotate and the workmen's clothing becomes saturated with it. Friction of the scrotum against the mule frame as the worker leans forward is the other factor concerned. Women who work in this department are not affected.

About 70 per cent of all cancers seen in mule spinners are on the scrotum. It is strange but it would appear that no cases of this particular cancer have been reported in France, Germany, Russia, or Poland while it seems to be rare in the United States.

The true paraffin cancer arises in workers in the paraffin department of the shale oil industry. Various earlier lesions occur sometimes within a few weeks after the worker is employed in this department.

The lesions disappear in a short time if the employee ceases to work with paraffin but they persist in greater or lesser degree as long as the men continue to work in the department. The early lesions may be comedones but much more common is an inflammation of the mouths of the follicles. This is the characteristic shagreen skin which occurs not only in paraffin workers but also in mule-spinners and the author has also seen it in a worker in a ropery where mineral oil was used. One other feature completes the picture and that is the presence of warty lesions. The important point about this lesion is that it may develop many years after the worker has ceased to be employed in the paraffin department. These warts are the precursors of carcinoma though it may also arise from indurated papules.

With regard to the actual cause of the carcinoma it is definitely established that it consists in the contact with the oily paraffin scale as the scale itself has been proved not to be the cause. The oil is the agent which provokes the changes in the skin which eventually lead to the cancer.

The prophylactic measures adopted at the Scottish Oil Works have been efficient and successful. Each man has a bath after quitting his work. Soiled working clothes are put into lockers which are heated and are thus dry before the men resume work next day. A rigorous selection of the men employed in the paraffin department is made all showing an early tendency to paraffin eruptions being removed and sent to other departments.

What has been done in this industry may be done in others. Admittedly the number of men employed in the paraffin department of Scottish Oils is not large, but mere numbers should not be allowed to stand in the way of measures designed to prevent such a serious industrial hazard. The willing cooperation of employers, employees and medical men is essential to the success of such a scheme.

JOHN F. KIRKPATRICK, M.D.

Butler A. M. and Talbot N. B.: Medical Progress: Parenteral Fluid Therapy. Estimation and Provision of Daily Maintenance Requirements. *V. England J. M.* 1944, 331-385.

The last fifty years have witnessed a steady increase in knowledge concerning the metabolic disturbances resulting from starvation and dehydration. In addition, the increased availability of specific nutrients and of solutions through parenteral administration has increased not only the possible effectiveness of parenteral nutrition and repair therapy but also the physician's responsibility in the parenteral administration of fluids. This review presents in outline form such basic data as may be helpful in effectively utilizing this knowledge in the parenteral therapy that is at hand today or may become available tomorrow.

Tables 1, 2, and 3 best present these basic facts.

As to the manner and rate of parenteral administration, the authors state that since information regarding many factors concerned with optimal utilization of such nutrients is lacking, the prescription of the rate of infusion and composition of parenteral fluids for a given patient must reflect common sense.

TABLE 1—APPROXIMATE NORMAL SODIUM CHLORIDE MAINTENANCE ALLOWANCES PER DAY FOR RESTING NONSWEATING PERSONS OF VARYING SIZE

Size	Sodium Chloride	Physiological Saline Solution
	gm.	cc.
Infants		5
Children	5	350
Adolescents and adults	6	700

TABLE 2—APPROXIMATE DAILY CALORIC REQUIREMENTS OF NORMAL RESTING PERSONS OF VARYING SIZE, TOGETHER WITH THE DAILY DEXTROSE AND AMINO ACID ALLOWANCES* THAT THEORETICALLY MIGHT SATISFY THEM

Size	Daily Caloric Requirement	Daily Dextrose Allowance		Daily Amino Acid Allowance	
	al. 2 gm.	gm./kgm.	cal./kgm.	gm./kgm.	al./kgm.
Young infants	60	6	54	5	6
Old infants	33	5	5		4
Children	5	7	8	6	
Adolescent and adult	5			6	

* A solution does not suggest 5 gm. of amino acid 100 cc. of solution should allow for the adult but for estimating the daily allowance for the younger (less) best on high carbohydrate diet is average.

TABLE 5—APPROXIMATE NORMAL WATER LOSSES AND ALLOWANCES PER DAY FOR PERSONS OF VARYING SIZE NOT SUBJECT TO EXERTION OR SWEATING

Size	Water Loss				Usual Water Allowances		
	Urine	Stool	Insensible	Total	cc/person	cc/kgm	oz/lb
	cc	cc	cc	cc	cc/person	cc/kgm	oz/lb
Infant (to 10 kgm)	200-300	5-20	15-300†	300-320	120-1800	65-100	2-4
Child (to 40 kgm)	300-800	20-100	300-600	620-1400	600-1800	100-45	3-6
Adolescent or adult (60 kgm)	800-1000	00	600-1000†	1400-2000	800-2000	45-70	3-6

DUCTLESS GLANDS

Finkler R. S. Furst N. J. and Klein M. A. Clinical and Roentgenological Study of the Effects of Hormonal Therapy on Bone Growth. *Radiology* 94:4, 43-54

Observations on the rate of bone growth were made not only on children treated for growth deficiency but also on those showing hypogenitalism, cryptorchidism, pseudo-Froehlich's syndrome, obesity and mental retardation. Clinical observations of growth and of genital and somatic development were recorded prior to and during, and after therapy routine roentgen studies of the skull, sella turcica and long bones were made at regular intervals. The skeletal age was estimated by the epiphyseal development of the distal ends of the radius ulna, metacarpals and the phalanges of the hands, by the presence of the centers of ossification and the number of carpal bones. The progress of skeletal development was judged in accordance with the standards of Todd. The degree of mineralization was estimated by the standards established for the study of osseous structures.

These studies were carried out on a group of 81 children of whom 65 were clinic patients and 16, private patients. The therapeutic agents employed were thyroid substances (in 18 children), extract of the anterior lobe of the pituitary gland (in 36 children), chorionic gonadotropin (in 10 children), and male sex hormone (in 18 children). The effect of the various hormones on skeletal growth, bone density and epiphyseal union was noted.

Before hormonal therapy all of the children presented various psychological maladjustments most of them were shy, self-conscious, and unsocial. Others were resentful toward their parents, guardians or society in general. Following successful endocrine therapy with improvement in growth and genital and muscular development there was a tendency to improvement in mental and emotional stability.

EARL C. ROSENTHAL, M.D.

Glute, H. M. and Williams, R. H. Thiouracil in the Preparation of Thyrotoxic Patients for Surgery. *Ann. Surg.* 1944, 120: 504.

The authors report their experience with thiouracil in 115 thyrotoxic patients. 81 of whom were treated without surgery, the remaining 34 were treated with thiouracil and surgery. The medically treated patients experienced, for the most part, an early return to normal without further toxic manifestations unless iodine had been taken for a long time previously.

Of the 34 surgical patients, 4 had toxic adenomatous goiter, the others had typical uncomplicated exophthalmic goiter. Surgical patients were treated for 6 to 8 weeks preceding thyroidectomy, were usually operated upon after two days of hospitalization, and returned home six or seven days after operation.

Certain patients, perhaps 10 per cent, have complications from thiouracil of sufficient degree to necessitate discontinuation of the drug. The most serious complication are agranulocytosis, leukopenia, morbilliform rash with itching, and nausea and vomiting.

During the period of preoperative preparation, usually the thyroid gland became smaller and firmer. The active pulsations, thrills and bruits tended to disappear. In some cases, however, the goiter seemed to become larger as treatment progressed but this was unusual. In most patients having a stare and a widened palpebral fissure, improvement in the eyes occurred as their general condition improved. In individuals showing manifestations of malignant exophthalmos, apparently the minimal effective dose of thiouracil should be used to bring the metabolism to normal. Over-treatment may lead to an increase in the exophthalmos.

At the time of operation the thyroid gland in thiouracil treated patients is firm and resembles the consistency of the untreated hyperplastic thyroid. It is not as vascular as in untreated patients, although the superior and inferior arteries are still of large caliber. The tissue surrounding the gland is at times densely adherent to it and cleavage planes are hard to establish. More bleeding is encountered in some of the thiouracil-treated patients than in the iodine treated patients.

Histologically the thiouracil treated hyperplastic gland showed very little colloid. The cells of the acini were tall and columnar. Many of the acini were small and contracted, only a few showing papillary projections. There seemed to be an increase in interstitial tissue between the acini. There was little histological difference between the glands of patients treated only a few weeks and the glands of patients treated over a period of many months. In patients who received both iodine and thiouracil there were definite increases in the colloid contents of the acini as compared to the findings in patients who had received no iodine.

The operative course in thyrotoxic patients treated for five or six weeks with thiouracil is characterized by its smoothness. Like patients with a normal metabolism, these patients react to a moderate surgical procedure with no outstanding changes in the pulse or blood pressure and with a postoperative course that is smooth and uneventful. The nervousness, activation and severe tachycardia were entirely absent in the authors' cases. The induction and maintenance of anesthesia are the same as in any patient with a normal metabolism. Cyclopropane-oxygen has been the anesthetic of choice in all of the authors' patients.

STEPHEN A. ZIEGLER, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Wills, R. A.: The Mode of Origin of Tumors. Solitary Localized Squamous-Cell Growths of the Skin. *Cancer Res.*, 1944, 4: 630.

The most prevalent view concerning the mode of origin of tumors is that each tumor has a simple unicentric origin arising at a single point in time from a single small focus of cells and that it enlarges only by multiplication of these cells and their descendants.

To test this theory the author studied the structure of 10 early localized, solitary squamous-cell carcinomas of human skin, and came to the conclusion that the structure of these growths was incompatible with a strict unicentric view regarding their origin, and that, instead, the structure showed that each has arisen by spreading cancerization of a field of epidermis.

The precancerous state of an area of skin includes significant dermal changes, especially in the subepithelial elastic tissue, and invasion of the dermis by the cancerous epithelium probably commences at points of greatest damage to the dermal elastic.

Progressive neoplasia in a field of tissue does not imply the passage of any carcinogenic stimulus from cell to cell, but is merely the progressive response of an area of epithelium to the same original stimuli, the timing and distribution of this progressive response depending on the distribution and intensity gradients of the causative stimuli.

The author believes that the evidence advanced justifies the view that squamous-cell carcinomas of the human skin are comparable with those produced

experimentally and that they are the products of the following sequence of events:

- 1 A skin field more or less extensive, has been subjected to a succession of carcinogenic stimuli (still often unascertainable in human beings) which have induced slow progressive changes in both the epidermis and dermis of that field and are structurally apparent as precancerous hyperplasia.

- 2 At the central focus (or at several high potential foci) of the field, hyperplasia passes into irreversible neoplasia, with or without immediate invasion of the dermis by the epithelium.

- 3 As cancerous proliferation and invasion progress at the central part of the field, cancerous change of the surrounding unstable epidermis takes place in a steadily enlarging area around the center.

- 4 After the entire field of the predisposed epithelium has become cancerous the tumor enlarges solely by proliferation of the cancerous cells and structural evidence of its mode of origin is soon lost.

The author strongly emphasizes the point that a skin cancer in its early formative stage arises more by a gradual transformation of pre-existing epidermis than by cellular multiplication and that only after the formative field has all suffered neoplastic change does the tumor grow solely by multiplication.

JOSEPH K. NABAT, M.D.

Berenblum, I.: Irritation and Carcinogenesis. *Arch. Path., Chic.*, 1944, 38: 233.

In this review the author carefully defines his terms and poses a series of questions which he answers by logical reasoning and by known clinical and experimental evidence in an attempt to arrive at the relationship between irritation and carcinogenesis.

The first question presents the problem in its crudest form: Are all irritants potentially carcinogenic? An affirmative answer would mean that irritation plays an essential part in the production of tumors while an answer in the negative would mean that irritation is not by itself responsible for tumor formation although it might play a vital part in carcinogenesis. With certain physical agents designated by the term "radiation," including roentgen rays, gamma rays, and ultraviolet rays, there is an apparent correlation between their power of producing injury to tissue and their ability to induce tumors. Of many chemical irritants tested only a small proportion have been found to possess carcinogenic action. Trauma in the sense of one or a few mechanical injuries cannot be accepted as an important or frequent cause of tumor formation in view of the extreme frequency of traumatization and the extreme rarity of tumors of proved traumatic origin. In regard to a relationship between long continued friction and tumor formation, the operation of other factors sometimes makes the answer difficult, but chronic mechanical irritation (friction) cannot be accepted as a common or even likely cause of tumor formation. The relation of thermal injuries to carcinogenesis is complicated by the fact that they do not represent a single entity but the available

evidence is more convincing than that concerning mechanical injuries. Both burns and repeated freezing have been demonstrated to be carcinogenic. Other experiments do not support the view that irritation itself is a deciding factor in carcinogenesis and, thus, the answer to the question "Are all irritants potentially carcinogenic?" is emphatically No.

The second question is "Are all carcinogenic agent irritants?" This question requires a definition of what is meant by irritant. If by "irritation" is meant the production of a continued state of reparative hyperplasia which is the meaning as defined in this review then all the direct carcinogens, without exception, are irritants. One is thus brought back to the central problem of hyperplasia. What does it represent? How does it differ from neoplasia? And what evidence is there that preneoplastic hyperplasia is biologically different from reparative hyperplasia? Hyperplasia and neoplasia are both cellular proliferation in excess of the normal. The distinction lies in the extent or limit of growth. Knowledge of the development of occupational tumors in man and experimentally induced tumors in animals points to the occurrence of a preneoplastic hyperplasia preceding the development of a tumor. The conclusion already reached that all direct carcinogens are irritants means when translated into terms of response that all tumor-producing agents are also hyperplasia-producing agents. These facts taken together indicate that hyperplasia is an invariable and essential preliminary to neoplasia. But it has already been shown that not all irritants are carcinogenic. Therefore, preneoplastic hyperplasia must be a special kind of hyperplasia biologically distinguishable from ordinary reparative hyperplasia. Further the experimental evidence that preneoplastic hyperplasia is of a specific type is convincing.

It is conceivable that the development of a tumor out of normal tissue could be a sudden change or it could be dependent on a sequence of separate specific biological reactions. In the neoplastic transformation of the skin of the mouse or rabbit following application of a carcinogen, three distinct phases can be recognized: (1) the prewart stage during which hyperplasia is the dominant lesion, (2) the stage of benign tumor growth during which one or more papillomatous structures appear and grow and (3) the stage of cancer when one of the latter structures starts to infiltrate the subepithelial tissues. The question arises as to whether the three phases are consecutive stages of a single carcinogenic process, or are they consecutive but separate processes? Several methods of approach have been used in an attempt to answer this question. The balance of evidence is in favor of the view that prior to the establishment of cancer continued stimulation enhances the carcinogenic process. The experimental data are tabulated in three groups of results: (1) the irritant and the carcinogen are applied concurrently, (2) the irritant is applied for a period preceding the application of the carcinogen and (3) the irritant is

applied after the application of the carcinogen has been discontinued.

The effect of applying another irritant concurrently with a carcinogen varies according to the irritant used, but most irritants seem to have no significant influence when applied in this way. This is further evidence that intensity of irritation is not the deciding factor in carcinogenesis. These experiments bring to light the existence of specific cocarcinogenic agents and equally specific anticarcinogenic agents. More precise information is derived from experiments in which the application of the irritant either precedes or follows the treatment with carcinogen. Ordinary irritants generally prove unsuccessful in producing a preneoplastic lesion of the skin, but many of them seem able to precipitate a tumor once the preneoplastic state has been established. The balance of evidence is therefore strongly in favor of the view that the component phases of carcinogenesis are consecutive but independent processes.

Thus the evidence indicates that preneoplastic hyperplasia is a highly specific type of hyperplasia since only carcinogenic agents can produce it with certainty but that once the preneoplastic stage has been induced by a true carcinogen a benign tumor can be made to appear at that site and a tumor already present can hasten its progress to carcinoma by the action of a variety of noncarcinogenic irritants. If this is confirmed the following practical lessons will have been learned: (a) there is little danger that an ordinary irritant will produce a tumor of its own accord, (b) this applies also to the initiation of a preneoplastic lesion and (c) given a preneoplastic lesion the subsequent development of a benign tumor at the site may be facilitated, and its progress to cancer hastened, by the action of a variety of nonspecific irritants. With most nonspecific irritants this facilitation is far less effective than it is with a true carcinogen.

JOHN L. LANDOUST M.D.

EXPERIMENTAL SURGERY

Moyer, C. A., Collier, F. A., Job, V., Vaughan, H. H., and Marty, D.: A Study of the Interrelationship of Salt Solutions, Serum, and Debrinated Blood in the Treatment of Severely Scalded Anesthetized Dogs. *Ann. Surg.* 944, 20, 167.

Saline-bicarbonate solution is more effective than Ringer's-lactate solution, and Ringer's-lactate solution is more effective than "isotonic" sodium-chloride solution in prolonging the life of anesthetized dogs when an amount of these solutions equal to 10 per cent of the animals' body weight is given intravenously before the animals are scalded (two-thirds body surface at 85 C. for thirty seconds). The presence of the bicarbonate ion or the potential bicarbonate ion in the lactate solution appears to be responsible for the superiority of the Ringer's-lactate and the saline-bicarbonate solutions.

The combination of massive transfusions of debrinated blood and oral administration of saline-

bicarbonate solution was the only form of therapy employed that prevented shock without inducing complications that were incompatible with life.

The other forms of therapy employed namely (1) saline-bicarbonate (intravenous), (2) saline bicarbonate (intravenous) and serum (intravenous) (3) serum (intravenous) and saline-bicarbonate by stomach and (4) defibrinated blood (intravenous) and water ad libitum prolonged life and in a number of instances prevented shock. However all of the animals that did not die of shock during the first twenty-four hours died later of complications that seemed to be related to the therapy rather than to the trauma.

A hematocrit of from 80 to 85 per cent does not prohibit the use of transfusions of whole blood.

JOHN J. MALONEY, M.D.

Elman, R.: The Influence of Ether, Morphine and Nembutal on the Mortality in Experimental Burns. *Ann Surg.*, 1944, 110: 211.

Experiments show that the early mortality following severe thermal injury is profoundly influenced by the type of sedation and anesthesia used. A series of experiments were carried out in which severe burn stimulus (immersion up to the axilla at 100 C. for ten seconds) was employed in a series of 10 experiments each. Various doses of morphine in combination with nembutal or ether were used in each group.

Morphine increases the twenty-four hour mortality (up to 100 per cent) in severe experimental burns particularly when given in large doses and with nembutal. Practically no twenty-four hour mortality occurred when ether alone was employed. It is inferred that large doses of morphine when used in the absence of pain may increase the early mortality in severe human burns.

LOUIS T. BYRNE, M.D.

HOSPITALS; MEDICAL EDUCATION AND HISTORY

Adams, J. M.: Stanocola Medical Care Plan. *J Am M Ass* 1944, 126: 333.

The features of the Stanocola Medical and Hospital Association are as follows:

1. It was conceived and organized and is owned, supported and operated by employees.
2. Membership is entirely voluntary.
3. It supplies necessary medical hospital and nursing services to employee members and to their families.
4. There is only one rate of dues regardless of the number of dependents.
5. The medical staff is on salary and mainly on full time.

Although it is owned and operated by the employees the company is much interested in its success and lends its support by

1. Making payroll deduction of the dues.
2. Permitting deduction of the dues from the company thrift fund. This fund is supported by

regular voluntary contributions by employees and by the company. Dues collected from this fund as 85 per cent of them are, represent both employee and company contributions. Through the medium of this fund, members of the association thus receive material help from the company in the payment of their dues.

3. The company has aided the association substantially by making a large donation toward the purchase of its clinic building and on other occasions has made contributions for special purposes.

4. The board of directors of the association has always included two or more of the company's executives elected by the membership. The association is entirely distinct from the company's medical department whose work is limited to industrial medicine—preventive medicine and the care of industrial injuries and diseases.

This plan was put into effect in April 1924 as a result of the reduction of income on the part of the employees of the company who had been unable to secure a reduction in prices and fees to equalize their loss of income. At this time the project was placed on an experimental basis since there were then no Blue Cross hospital plans. The first arrangement was one in which 1,300 employees made an agreement with 4 physicians to pay a retainer of one dollar annually per membership. The physicians divided this fund and agreed to treat the subscribers for one half of the usual fees. This arrangement was unsuccessful and therefore was not renewed after one year.

The Stanocola Medical and Hospital Association was then formed with 2,200 subscribers. In the beginning arrangements were made with private practitioners to treat those eligible in the doctors' own offices. In the panel were a surgeon who served as medical director and an ear, nose and throat specialist. After six months of operation clinic space was rented and all of the physicians except the surgeon and medical director were included on this basis. In 1931 larger quarters were obtained and the staff increased to 11 doctors on full time and 5 on part time. In addition to the medical staff 6 nurses, 2 laboratory technicians, an x-ray technician, 2 office girls, and a cleaning staff were employed and a couple living in the garage answered telephone calls when the offices were closed. The character of the medical staff is excellent, all members being graduates of approved medical schools and most of them having had postgraduate training.

Aid provided starts with medical and surgical services limited only by the capacity of the staff. Patients are treated in the clinic, in the hospitals or in their homes within a radius of seven miles of the clinic, as indicated. Beyond the 7 mile limit a small mileage fee is paid by the patient to the doctor. Hospitalization is at ward rates except that private rooms are provided for contagious diseases and when privacy is a necessary part of the treatment. The general hospitals in Baton Rouge are used and

accord special rates to the association. Special nurses are provided when they are considered necessary. Hospitalization and nursing costs are limited to \$250 for each case.

The average cost to each member of the Association per month is \$3.50.

The advantages to the members are as follows:

1. The members of the association have adequate medical, hospital, and nursing care for themselves and for their families at a predetermined cost. The total cost is probably as great as if the group purchased the service individually, but it has probably received more service than it would have purchased as individuals.

2. The members have been supplied with services at least the equal in quality of that otherwise available and superior to that usually received by persons in the same economic group. They have had the advantage of much freer consultation with specialists than they would have had otherwise, and laboratory and x-ray examinations are more freely used.

3. They have escaped a not infrequent cause for strangling debt—large medical and hospital bills.

4. They have the satisfaction of providing this care for themselves and their families by their own efforts rather than having it handed to them.

The advantages to the employer are as follows:

1. Adequate medical care for the employee is provided with return to duty with the minimum loss of time.

2. Close co-operation exists between the company's medical department and the employee's physician.

3. It is easier to persuade employees to have physical defects corrected than it would be otherwise.

4. Fraudulent claims of industrial injury are reduced.

5. The morale of the employees is improved by freedom from worry over costs of illness and by the satisfaction of providing such excellent medical care through their own efforts.

The advantages to the medical staff of the association are:

1. The compensation is probably higher than the average in the community in normal times.

2. The inconvenience of carrying on an individual business is avoided.

3. Each physician has one day off each week and an annual vacation with pay.

4. Postgraduate training at the expense of the association is provided on occasions.

5. The close association and consultation with other physicians stimulates them to better work.

BENJAMIN GOLDBMAN, M.D.

April, 1945

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

HEAD

Wissenfeld, I. H. and Phillips, E.: Thrombophlebitis of a Cavernous Sinus following the Extraction of Teeth: Cure with Penicillin and Heparin. *Arch. Otolar., Chic.* 1944 40 497

Prior to the day of sulfonamide therapy recovery from thrombophlebitis of a cavernous sinus was extremely rare. With the advent of these compounds reports of cures began to appear following the administration of sulfanilamide, sulfapyridine, sulfathiazole, and presumably, sulfadiazine. The use of anticoagulants, especially heparin as adjuvant therapy seemed to enhance the value of the sulfonamide compounds but this was by no means proved. Recovery from cavernous-sinus thrombophlebitis with penicillin therapy has been reported.

The case reported by the authors illustrates again the danger of performing an operation on the maxilla and the palate in the presence of acute sinusitis. Thrombophlebitis of a cavernous sinus developed in the presence of an adequate sulfadiazine level in the blood. A dramatic recovery followed the administration of penicillin and heparin.

EYE

Pfeiffer, R. L.: Localization of Intraocular Foreign Bodies by Means of the Contact Lens. *Arch. Ophth., Chic.*, 1944, 33 261

The author discusses the roentgenological localization of intraocular foreign bodies with the aid of a contact lens. The lens which is made of plastic material, is of average scleral radius (21 mm.) and corneal radius (8 mm.).

In Vogt's method of taking bone-free roentgenograms for localizing fragments in the anterior 8 to 12 mm. of the eye an ordinary dental film is held over and perpendicular to the inner canthus and the rays are directed from the side so that a shadow of the profile of the anterior segment of the eye is recorded.

The method which utilizes the contact lens with radiopaque markers is recommended as most ac-

Fig. 1. Lateral view of an intraocular foreign body with a line drawn anterior to the markers to indicate the plane of the limbus (EF). GH is drawn at right angles to EF and through the foreign body indicated by an arrow.

curate. It requires 2 roentgenograms, a postero-anterior and a lateral.

After these are taken lines are drawn on the films to indicate the relationship of the foreign particle to the contact lens, and the location is then shown on charts that represent an anteroposterior view of the eye and a cross-section cut in the meridian in which the foreign body lies. The position of the foreign body is plotted by drawing a horizontal line on the x-ray film across the orbits several millimeters below the upper margins, then drawing a horizontal and vertical line through the shadows of the markers on the contact lens to locate the center of the lens. A line is then drawn to bisect the foreign body and pass through the center of the lens. The angle formed by this line with the horizontal line through the upper part of the orbit is measured with a protractor and a corresponding line at this

intramuscular injections of 150 units in 2 cc. of saline solution every three hours for a period of forty-eight hours. Experimental work indicates that this probably gives a concentration of penicillin in the tissues that is too low to be effective, and that probably much larger doses must be used if they are to be of any value. This is borne out by the clinical results, which have been most disappointing in the treatment of posterior uveal infections.

The results obtained in the treatment of infections of the anterior segment of the eye by topical instillation of penicillin are much more encouraging. Aqueous solutions require very frequent use and an ointment would appear to be the most satisfactory. Four ointments were tested for their penetrability: simple ointment, oil-in-water, emulsion, and lubricating jelly. They were found effective in the order named. Penicillin showed the greatest penetrating power when placed in a "vanishing" stearate type of base and while this may be used on the skin of the lids, its use on the conjunctival sac is not advised because of possible damage to the corneal epithelium. The simple ointment found best for conjunctival use was made by adding 25,000 units of penicillin dissolved in 0.25 cc. of distilled water to 10 gm. of simple ointment (U.S.P.). It is advisable to make up no more than is required for a twenty-four to forty-eight hour period and to keep the ointment on ice, because the substance usually deteriorates at a rapid rate.

Penicillin used locally was found effective in the clinical treatment of acute and chronic infections of the lids, conjunctiva, and cornea which had been produced by penicillin sensitive organisms. In 10 of 12 cases of acute staphylococcal conjunctivitis the condition was cured within forty-eight hours. Cases of chronic conjunctivitis which had resisted ordinary methods of treatment for months or years were usually arrested within a week. In the acute cases hourly applications of penicillin day and night, are most effective. In the chronic cases it should be applied during the waking hours only.

It is pointed out that susceptible individuals may become hypersensitive to penicillin. This heretofore unreported occurrence was noted in 4 of the 46 patients who received treatment.

Benham, T. M.: The Conservative Treatment of Chronic Suppurative Otitis Media in Adults. *J. Laryngol.*, Lond. 1944 59 117

Cases of chronic suppurative otitis media constitute a large part of the cases coming to the outpatient department at ear, nose and throat centers of the R.A.F. The results of treatment of 200 consecutive unselected cases are presented.

The method of treatment was based on the thesis that thorough cleaning of the ear was most essential. For best results endaural manipulations should be carried out personally. Aural polypi and granula-

tions were removed. Flat granulations were cauterized with trichloroacetic acid and the middle ear was emptied by suction through a cannula by means of eustachian inflation, after which dry powder was insufflated. Sulfathiazole powder seemed preferable to boric powder with 1 per cent iodine. A gauze wick soaked with antiseptic solution was left in the meatus.

The treatments varied from twice a day to once a week, the wick being removed after forty-eight hours or when soaked.

Eighty-two and one-half per cent of the ears became dry. 8 1/2 per cent became quiescent, and the remainder were unaffected. Those with central perforations became dry in over 90 per cent of the cases; those with attic perforations became dry in 83 per cent, and with marginal perforations in 49 per cent. Central perforations not involving the fibrocartilaginous ring surrounding the pars tensa were found in over 66 per cent of the cases and these responded best to conservative treatment. The attic perforations usually had localized disease in the anterior or posterior pouch of Troeltsch or in Prussak's pouch. When the perforation was large the prognosis was good, but extensive cholesteatoma could not be cured without surgery. Marginal perforations respond poorly because of bone necrosis. Polypi or granulations arising from the tympanic cavity were evidence of diseased bone and usually required surgery. The majority of the ears in the successful cases became dry in less than one month. Ears which had not become dry after two months of continuous and thorough treatment usually required surgery.

JOHN R. LINDSAY, M.D.

Hall, I. S.: The Surgical Treatment of Otosclerosis. *Proc. R. Soc. M.*, Lond. 1944, 37 737

The main object of surgery for otosclerosis has been to replace the immobilized stapes by a movable membrane, but whether this is justified is still open to question.

The author has experimented with placing the fenestra first over the canal, but he has placed it over the ampulla in all his latest cases.

Local anesthesia is used to the stage of opening the labyrinth when pentothal sodium is given intravenously as long as necessary.

The results of 66 operations are difficult to evaluate since various techniques were used, but it was found that if improvement is maintained for four months after the operation it is likely to persist for some time.

There have been very few complications and these were of a minor nature. No cases of facial paralysis or labyrinthitis were reported.

The selection of patients influences the results greatly; the younger seem to do better. Reliance is placed on the use of the monochord for determining bone conduction in the higher frequencies. Lack of appreciation of the upper tones by bone conduction has proved to be a contraindication to operation.

JOHN F. DIXON, M.D.

angle is plotted on a chart representing the front view of the eye. Then the distance of the foreign particle from the center of the contact glass is measured with a compass and millimeter rule. This measurement (minus a correction for the magnification of the lens) is transferred to the chart. It represents the distance of the foreign body from the anteroposterior axis of the eyeball. The correction factor depends on several variables.

On the film of the lateral view (Fig. 1) a line (EF) is drawn across the shadow of the contact lens anterior and tangential to the markers of the lens so that the limbus is located. Another line (GH) is drawn perpendicular to the first through the foreign body and the distance along the line from the foreign body to the plane of the limbus is measured. This measurement (corrected for magnification) represents the actual distance of the foreign body behind the plane of the limbus.

The location of the foreign body is plotted on a chart which represents a front view and also a section of the eyeball. To increase the accuracy in plotting, the charts are made three times the normal size of the eye. Before making the incision for removal of the foreign body the surgeon should use a Gohst protractor to mark the exact meridian in which the foreign body lies, utilizing peripheral scratches on the cornea stained with fluorescein.

JOSHUA ZUCKERMAN, M.D.

Smolzer, G. K., and Ozanian, V.: Chemotherapy and Corneal Burns. *Am. J. Ophth.*, 1944, 37, 1003.

The purpose of this study was to determine which of the chemotherapeutic agents applied locally to the cornea interfered least with the reproduction of healthy epithelial cells or with the migration of these cells over a denuded area following an injury. This was carried out by counting the cells in mitosis in control eyes and in those treated with the sulfonamides and penicillin. Standard burns or abrasions were produced in one eye of rats the opposite eye being used as a control. Abrasions were produced in the form of a 1 mm. band of removed epithelium from limbus to limbus. Burns were made with the Shaban thermophore at a constant temperature and applied for a constant duration of time. The sulfonamides were applied as fine powders or as a 5 per cent ointment in a lanolin base.

Most of the sulfonamides had no deleterious effect on the cell-division rate in the intact cornea no matter in what form they were applied. Penicillin, likewise, showed no effect in these cases. It was concluded that the corneal abrasions healed without a marked increase in the number of mitotic figures. Thermal burns became covered in about the same length of time as did abrasions (from twelve to eighteen hours) but a great increase in the number of mitotic figures occurred in the process. Sulfacetamide, sulfapyridine, and penicillin had no effect on cell division in the intact rat cornea. Sulfadiazine seemed to increase cell division, and sulfathiazole to depress mitosis.

In general, the chemotherapeutic agents tested had no unfavorable effect on the abraded cornea and did not interfere with cell division in burned corneal epithelium. Sulfathiazole and sulfacetamide inhibited cell migration following corneal burns, whereas sulfadiazine and penicillin were but slightly detrimental. The sulfonamides used in the form of ointments inhibited cell migration slightly less than those used in powder form.

WILLIAM A. MANN, M.D.

Kayes, J. E. L.: Penicillin in Ophthalmology. *J. Am. M. Ass.*, 1944, 126, 610.

The contents of this article were gathered at the special penicillin research center at Bushnell General Hospital, Brigham City, Utah, from private communications of medical officers of the Army and from medical literature on penicillin. The research was carried on to determine the usefulness of the drug in ophthalmology.

As a result of the appraisal of penicillin, a study of the illustrative cases treated, the research on medication and dosage, and the notations of complications following its use, the following are some of the comments the author has made:

1. Penicillin is the drug of choice in the treatment of ophthalmic diseases secondary to infection with gonococci, streptococci, and sensitive staphylococci; it should be tried also in diseases caused by bacteria meningitidis, micrococcus catarrhalis, and pneumococci.

2. Penicillin, when effective, affords relief, usually promptly and sometimes startlingly. This relief is often better than that from other types of treatment.

3. Penicillin can be saved in considerable amounts by identifying the bacteria before treatment is instituted.

4. Penicillin is recommended as a prophylactic in certain intraocular operations and ocular injuries.

5. Penicillin given early and in large doses, is indicated in orbital cellulitis secondary to paranasal sinus infection and infection involving the venous dural sinuses.

6. Penicillin solutions because of their instability do not lend themselves to office and home medication as readily as more stable drugs. Penicillin ointment is reasonably stable for at least a month at room temperature and for six months in a commercial refrigerator.

7. Penicillin is destroyed by heat; therefore sterilization is not feasible.

LEONARD L. MCCOY, M.D.

Ballows, J. G.: Penicillin Therapy in Ocular Infections. *Am. J. Ophth.*, 1944, 37, 205.

Only by the injection of large amounts of penicillin intramuscularly or intravenously can a measurable amount of penicillin be found in the posterior portion of the globe of the eye. In cases of infections involving this portion of the eye, it has been recommended that 100,000 units be administered intravenously over a seventeen hour period, followed by

intramuscular injections of 1250 units in 2 cc. of saline solution every three hours for a period of forty-eight hours. Experimental work indicates that this probably gives a concentration of penicillin in the tissues that is too low to be effective, and that probably much larger doses must be used if they are to be of any value. This is borne out by the clinical results, which have been most disappointing in the treatment of posterior uveal infections.

The results obtained in the treatment of infections of the anterior segment of the eye by topical instillation of penicillin are much more encouraging. NOSE AND SINUSES

Seltzer A. P.: The Nasal Septum; Plastic Repair of the Deviated Septum Associated with a Deflected Tip. *Arch. Otolaryng. Chic.* 1944, 40: 433.

The author reviews the embryonic development anatomy and physiology of the nose, and discusses the pathology of the nasal septum. He describes the surgical method necessary for correction of the deflected cartilaginous tip of the nose associated with a deviated septum and gives the technique in detail. The method consists essentially in the uncovering of the nasal framework before correction of the septal deformity is attempted. The skin over the bony and cartilaginous bridge, along with the tip, alae, and columella are thereby freed from the septal cartilage, the upper lateral cartilages, and nasal bones. When the septal cartilage has been brought back to the midline position and sutured to the columella the deformity of the nasal tip is corrected. The septum deformity is corrected by incision on the convex side and subperichondral removal of a narrow vertical strip of cartilage from the dorsum to the base followed by incision through the cartilage along its base. This allows the septal cartilage to straighten when sutures are used to approximate the wound edges. JOHN R. LINDSAY M.D.

MOUTH

MacGregor A. B., and Long, D. A.: Penicillin Pastilles for Oral Infections. *Brit. M. J.* 1944, 2: 686.

Penicillin contained in pastilles was used in the treatment of several types of oral infections. Each pastille contained 500 units of penicillin and its content in the saliva was estimated after periods of fifteen and thirty minutes. These studies showed the penicillin to be present in large quantities up to fifteen minutes after the pastille had melted in the mouth. The penicillin pastilles retained their potency three months after their preparation. Bacteriological studies revealed that it was possible to reduce greatly the number of bacteria in the mouth, and even to produce sterile cultures. Patients with ulcerative gingivostomatitis, acute streptococcal tonsillitis, and other types of postoperative dental infections were treated, as well as chronic streptococcal carriers.

The clinical and bacteriological effect of penicillin pastilles in 25 cases of Vincent's disease was noted. All of the patients became asymptomatic in twenty-four hours, with disappearance of the characteristic fetor. In forty-eight hours, the slough disappeared and all signs of inflammation were gone. Bacteriological studies showed rapid disappearance of the spirochaetes and the fusiform bacilli. After seventy-two hours, films showed a preponderance of epithelial tissue and few organisms.

Seventeen patients with acute tonsillitis, pyrexia, and the demonstrable presence of Lancefield group A hemolytic streptococcus were treated. In forty

eight hours, local and general symptoms were completely relieved. The bacteriological course paralleled the clinical course. Controls treated with serum and sulfonamides failed to show such striking improvement. The majority of chronic streptococcal throat carriers treated with penicillin pastilles gave negative cultures within seventy-two hours of treatment. However throat cultures became positive within six days after cessation of the penicillin applications. Three compound fractures of the jaw previously showing marked evidences of oral sepsis responded so rapidly to the penicillin pastilles that within twenty-four hours fixation and splinting of the mandible became possible. Severe ulcerations of the mouth associated with pneumococcal and hemolytic streptococcal infections healed rapidly and no organisms were demonstrable after twenty-four hours of treatment. Patients from whom the micrococcus catarrhalis, haemophilus influenzae, and hemolytic streptococcus were obtained from the tonsillar beds after tonsillectomy also responded well to the oral penicillin treatment.

NECK

Vasconcelos, E., and Barretto, P. De M.: Total Laryngectomy; Simplified Techniques with the Use of a Special Clamp Which Makes Possible the Removal of the Larynx and Pre-Epiglottic Space without Opening of the Pharynx. *Arch. Otolaryng. Chic.*, 1944, 40: 375.

A technique is described for a conservative total laryngectomy in which a special clamp is used this clamp permits removal of the larynx and pre-epiglottic space in a single block and makes the suture of the larynx simple and safe. In the preparation of the patient, morphine, scopolamine, and sparteine sulfate are given subcutaneously forty-five

Fig. 1. The original Vasconcelos clamp, especially devised for suture of the pharynx. Barretto modification of the Vasconcelos clamp consists in having teeth in both blades of the clamp instead of in only one blade. This aids greatly in preventing the escape of the pharyngeal mucus when the larynx is removed.

Fig. 2. Eighth step in the conservative technique removal of the larynx and suture of the pharynx.

minutes before operation. Anesthesia is induced one half hour later by a solution of tribromethanol in amylen hydrate (from 0.08 to 0.10 gm. per kilogram of body weight). Intratracheal insufflation of ether may be added.

The simple laryngectomy operation is done in a narrow field through a midline incision making an exposure from the hyoid bone down to the thyroid isthmus. The hyoid is sectioned and the mylohyoid muscles are separated for a distance of 1 cm. The trachea or cricoid ring is sectioned and the larynx dissected free from below upwards. The dissection of the posterior surface of the cricoid is carried up to the transverse fibers of the arytenoid transversus muscle, the pharyngeal wall is separated from the posterior surface of the thyroid cartilage and the superior cornua are cut across. By means of a hook passed up through the larynx the epiglottis is pulled downward so as not to be caught in the clamp which is then put in place to cut off the larynx and pre-epiglottic space from the pharynx. After removal of the larynx by incision along the concave border of the clamp, a continuous suture is temporarily passed beneath the clamp and held by the two ends while the clamp is removed then a continuous suture of chromic catgut No. 000 or 0000 is placed in the Cushing manner and reinforced by interrupted sutures. The temporary suture is then removed.

A second technique is described for cases in which the prelaryngeal muscles and hyoid bone are to be removed. A transverse incision is used at the upper

Fig. 3. Left, Placing of the second sutures in the Cushing manner (Eighth step). Right, Ninth step in the conservative technique approximation of the constrictor muscles of the pharynx.

third of the thyroid cartilage. The tracheal stump is later brought through a circular opening in the lower flap.

In this operation the hyoid bone is dissected free. All muscles attached to its superior border are cut with the electric knife the bone then being removed with the prelaryngeal muscles and larynx. The clamp is placed in position in a way similar to the former method the larynx cut free along its border and the pharynx closed as in the simple operation.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Larje, A., and Heinbecker, P : Nerve Degeneration Following Prolonged Cooling of an Extremity
Ann. Surg. 1944, 120 742.

The effects of prolonged immersion cooling have not been fully verified by experimentation. Twenty dogs were used for this study. The animals were placed in a hammock with one forelimb immersed in cold water for ninety-six hours. A temperature of 6°C. was maintained constantly during this time. The animals were then sacrificed at intervals up to three months.

Immediately after the immersion the limb was swollen and showed either complete or partial loss of sensation and motor power. The threshold of faradic stimulation increased until about the fifth day when a response could no longer be obtained. It gradually returned to normal by the sixteenth day.

The generalized edema in the earlier period persisted longer in the nerves—at least ten days. After the edema had subsided, histological study revealed that in addition to a questionable fibrosis of the cutaneous and subcutaneous tissues there was a marked degeneration of all the peripheral nerves.

The extensive nerve damage in the early stages without signs of inflammation or damage to the other tissues suggests that later degenerative changes in the other tissues are secondary to neural destruction and ischemia. Unless amputation of the area is to be performed, therapeutic refrigeration should be used only with consideration of the possible late effects.

Davis, L., Hillier F. Perret, G. and Carroll, W.
The Effect of Sulfonamides upon Experimental Gunshot Wounds Involving the Peripheral Nerves. *Ann. Surg.* 1944, 20 494.

War wounds are usually associated with rather extensive destruction of the tissues, as well as with fractures, and are contaminated or grossly infected. The liberal use of sulfonamide drugs, with débridement, is to be considered in an effort to control the course of the infection. In view of this, it was believed that the effect of sulfonamides upon the repair and regeneration of peripheral nerves should be determined. If the use of sulfonamide drugs would hasten recovery from infection, and therefore allow peripheral nerve repair at an earlier date—with no deleterious effect upon nerve regeneration—the ultimate functional result would be improved.

An experimental study was undertaken, in which gunshot wounds were produced in the sciatic nerve of cats. Débridement of the wound and simultaneous repair of the nerve were performed immediately and at various intervals, until forty-eight hours after the injuries. The gross appearance of the wounds treated surgically six hours after injury was indis-

tinguishable from that of wounds treated immediately after injury except for an occasional edema. Wounds which remained untreated for more than twelve hours showed characteristic signs of infection. Various sulfonamide drugs, including crystalline sulfanilamide, powdered sulfathiazole, and sulfadiazine, were introduced locally into the wound at the time of débridement.

In spite of careful débridement performed immediately after the injury the rate of infection and of formation of extensive abscesses was very high when the sulfonamides were not used in the wounds locally. The rate of massive infection increased, the longer débridement was delayed. Massive infection resulted in 38.2 per cent of the animals treated immediately after injury and in 31.9 per cent of the animals operated upon six hours after injury. The percentages of infection rose further the longer the interval became between injury and surgical repair.

In the animals treated locally with sulfonamides, infection developed in 5 per cent of those which had been treated immediately and in 10 per cent of those débrided after six hours and in 26 per cent and 55.5 per cent, respectively of the groups treated from twelve to eighteen hours, and from eighteen to twenty four hours after the injury.

It was believed that in some instances adhesions were firmer in those cases in which sulfanilamide had been used locally in the wound, in contrast to those cases in which it had not been used.

A further experiment was conducted by sectioning the sciatic nerve in cats, with aseptic conditions in one group and septic conditions in another. The developing infections were treated with the various sulfonamides and in some instances the nerve was merely exposed, the drug applied upon it, and the wounds observed at intervals thereafter.

The wounds treated with sulfonamide compounds were characterized by an increased amount of adhesions fixing the nerve to the surrounding tissues. This was a constant finding in those cases which had been sectioned and sutured, or in which a graft had been used to effect a repair and these adhesions occurred whether or not the operation had been performed with aseptic or septic technique.

A study of the points of suture revealed no conclusive evidence that the regeneration of nerve fibers, axon-cylinder formation, myelination, or the absorption of myelin decomposition products was changed by the use of the sulfonamide drugs.

HOWARD A. BROWN, M.D.

Tarlov I. M : Autologous Plasma Clot Suture of Nerves; Its Use in Clinical Surgery *J. Am. M. Ass.* 1944, 26 741.

Although nerve suture has been relatively satisfactory, it has some shortcomings. It is difficult to avoid the inclusion of nerve fibers in the sutures to

avoid knuckling of the fibers when the knots are tied, and to avoid axial rotation of the nerves at times when the sutures are inserted. Recently a fine tantalum wire has been used and although there is less fibrotic reaction, there are the same objections to the wire as to silk sutures. Recent experiments with fortified cockerel plasma clotted with chick embryo extract for approximating the nerve ends has given very good results. However, there was an appreciable inflammatory and fibrotic reaction in connection with this procedure.

The author studied the various tension strengths of various plasma compounds and chose to use autologous unmodified plasma around which there was very little inflammatory or fibrotic change. Certain difficulties were found in holding the ends of the nerve together during the application of the plasma, and after a long series of experiments a rubber mold was devised for this purpose. The use of the mold with the unmodified autologous plasma in the suture of peripheral nerves led to satisfactory functional recovery. Fourteen cases so treated are reported and in about half of these sufficient time has elapsed to draw satisfactory conclusions. Some of the cases were checked by chromaxia studies. From 2 to 3 fine tantalum-wire tension sutures were considered to be a further advantage when plasma was used for nerve suture. Clinical results are satisfactory and further work with this method should be encouraged.

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Wood, E. H., Jr.: Some Roentgenological and Pathological Aspects of Calcification of the Choroid Plexus. *Am. J. Roent.* 1944, 52: 358.

Calcified bodies seen in the x rays of the skull are likely to lead to some confusion unless they can be identified as normal structures. The pineal body is frequently seen in the midline. Occasionally however parts of the choroid plexus are calcified, especially at the glomus which is situated at the atrium of each lateral ventricle. The calcification thus seen is usually fairly symmetrical though it may vary in density on the two sides. The calcification is due to regressive changes in the choroid plexuses. These changes are quite common.

On examination of the calcified areas it was found that they were composed of psammoma bodies in the connective tissue of the plexus. These bodies are common in all the membranes of the brain and spinal cord, but when gathered together in the plexus they constitute bilateral areas of calcification. The areas have been described as similar to popped kernels of corn or a collection of tiny glass beads.

This plexus calcification has been found in children, and 2 examples are mentioned one in a child two and one half years of age and the other in a child three years of age. Both children were very abnormal mentally had convulsive seizures and were diagnosed as having forms of cerebral aplasia.

A case is reported also of calcification in the plexus of the fourth ventricle. This was probably a coincidental finding. Calcification in the plexus may be of clinical significance when displacement of it occurs which would indicate an expanding lesion. Most of the tumors suspected because of displacement of the choroid glomus have been posterior to it, usually in the temporal lobe or in the occipital lobe. Two examples are reported in this article.

The article is written by the successor of Cornelius Dyke who contributed so much to the interpretation of x ray films of the skull in the Department of Radiology of the Neurosurgical Institute of New York.

ADRIEN VERHUGGHEM M.D.

Horwitz, A., and Perroni, J.: Meningococcal Meningitis in Santiago Chile from 1941 to 1943; An Epidemic of 4,464 Cases. *Arch. Int. M.* 1944 74: 365

During an epidemic of meningococcal meningitis that occurred at Santiago Chile, in the years from 1941 to 1943 4,464 persons, or 1 of every 300 inhabitants acquired the disease. The authors have made a study of this epidemic from the viewpoint of mortality morbidity and treatment.

The mortality rate on patients was 16.5 per cent among adults and 28 per cent among infants under four years of age. The authors find fault with the words "epidemic cerebrospinal meningitis," and have adopted the designation of "meningococcal infection." The complications were not numerous because of the use of adequate chemotherapy. There were ocular complications in 5 per cent of the patients, and partial or total unilateral or bilateral deafness in 5 per cent. Other complications referable to the central nervous system were also seen. Arthritis involving one or more joints and varying from the simple painful joint to purulent arthritis, was observed in 10 per cent of the cases. Occasionally the arthritic involvement occurred late in the disease and the sulfonamide drugs apparently had little influence on it. Spinal puncture was performed for diagnostic purposes only. All strains of meningococci isolated from the patients corresponded to group 1 of Griffiths. Group 2 strains were isolated from carriers. Positive blood cultures were obtained in 9.7 per cent of the cases, and positive bone marrow cultures in 14.8 per cent. Chemotherapy was instituted early in the disease. The intrathecal route was not employed. If patients were rational, the oral route was preferred and gavage was used occasionally. For technical reasons blood levels were not obtained and, in any case, it was believed that the general condition of the patient was more important than the blood level.

The authors report the results of their studies on 450 patients divided into three groups of 150 each, which were treated with sulfadiazine, sulfanilamide and sulfathiazole respectively. Eliminating the patients who died within the first twenty four hours, the fatality rates were reduced to 10.7 per cent for the group treated with sulfanilamide, to 6 per cent

for the group treated with sulfathiazole and to 5 per cent for those treated with sulfadiazine.

With regard to the effect of therapy with these drugs, toxic manifestations were observed in 50 of the patients treated with sulfanilamide in 13 of those treated with sulfathiazole and in only 7 of those treated with sulfadiazine.

In conclusion, the authors state that at the present stage of our knowledge sulfadiazine appears to be the drug that is most satisfactory for the treatment of meningococcal infection.

ADRIEN VERBROECKEN, M.D.

SPINAL CORD AND ITS COVERINGS

Woods, W. W., and Piments, A. M.: Intramedullary Lesions of the Spinal Cord; a Study of 68 Consecutive Cases. *Arch. New Psychiat. Chic.*, 1944, 5: 383.

This is an analysis of 68 consecutive cases of intramedullary lesions of the spinal cord, in which operation was performed at the University Hospital, Ann Arbor, Michigan, between 1935 and 1943. In 4 cases the clinical diagnosis was not confirmed by operation, so that really 64 cases were confirmed and 35 of these presented intramedullary tumors. In 4 cases the histopathology was not obtained, in 5 cases there was a hemangiomatous tumor and in 20 cases syringomyelia was present. The symptoms were of relatively long duration in view of the location of the tumor. In 6 cases the symptoms were of ten years duration—they presented 2 ependymomas, mixed glioma, 2 dermoid cysts, and 1 spongioblastoma polare. These 6 cases produced widening of the neural canal in the roentgen pictures. Studies of the spinal fluid revealed block partial or complete in 25 cases. There was no significant correlation between the pathological type of tumor and the presence of

spinal-fluid block or of xanthochromia. There was not any special syndrome which differentiated intramedullary from extramedullary tumor although this statement is somewhat in contradiction to the usually accepted theory.

There are two points with regard to the treatment that the authors emphasize: (1) there should be a vertical chordotomy of the entire length of the tumor just to one side or other of the midline and (2) the dura should be left widely open for the purposes of decompression. In fact, they advocate transverse cuts in the dura as well as the longitudinal incisions. The authors have also compared their own series to those cases that they have found adequately described in the literature, and they are unable to be as optimistic, on the basis of their statistics, as the reports in the literature, especially with regard to complete operative removal of the tumor.

The tumors were classified histologically according to the method of Cushing and Bailey and the modification of Kernohan and various types of gliomas were found with the ependymoma predominance. Melanoblastoma, intramedullary blood clot, and dermoid cysts were also found. Roentgen-ray therapy appeared to be of most value in the ependymomas.

With regard to the patients with syringomyelia, the shortest duration of symptoms was ten days and the longest twenty-one years. The clinical examination confirmed the classical description of the disease. Treatment consisted of operation with vertical incision of the syringomyelic cavity. However, the ultimate results of treatment of syringomyelia have not been nearly as good in the authors' series of cases as the rest of the literature would suggest. There is an extensive bibliography and adequate statistical tables to confirm the points brought out.

ADRIEN VERBROECKEN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Webster G V: Gynecomastia in the Navy *Md Surg*, 1944, 95 375

In 1942 there was an incidence of 6.96 cases of gynecomastia in the Navy per 100,000 admissions.

The three most commonly ascribed causes of gynecomastia are (1) heredity (2) mechanical stimulation, and (3) hormonal imbalance. The author believes that only the latter two are responsible.

With hypertrophy of the breast in the male there is hyperplasia of periductile connective tissue and an increase of the epithelial lining of the ducts. These ducts may be dilated and even cystlike. Not infrequently, small adenomatous areas surrounded by dense fibrous tissue are present. The microscopic picture is indistinguishable from a fibroadenoma or chronic cystic mastitis in the female.

Treatment of the breast is indicated for cosmetic reasons, and for pain or disability resulting from the size of the enlargement. Endocrine therapy has at best produced only temporary regression.

The author preserves the nipple for psychic reasons. The breast tissue is removed through a tiny circumareolar incision in the lower half of the areolar circumference. Very large masses of breast tissue can be removed through such an incision if the specimen is removed in quadrants or sixths one piece at a time. Care must be taken that no breast tissue is allowed to remain. Hemostasis is secured by pressure and if necessary by suture ligation. Pressure dressings with an abundance of fluffed gauze are applied to prevent postoperative edema and hemorrhage.

EARL O LATIMER, M.D.

TRACHEA, LUNGS, AND PLEURA

Weems, H. S.: Pulmonary Disease Associated with Megacosophagus. *Am. J. Roentg* 1944, 52 472

During the past four years the author has encountered 15 cases of megacosophagus in the Grady Hospital of Atlanta, Georgia. In 5 of these pulmonary complications were demonstrated roentgenologically. Although this incidence may be too high, judging from such a small series of cases, nevertheless it is the author's impression that pulmonary lesions occur in megacosophagus more often than is generally appreciated. The complications in the 5 cases, which are individually reported, represented pulmonary abscess, aspiration pneumonia (in 3 cases), pulmonary fibrosis and bronchiectasis.

The interesting feature is that in 3 of the 5 cases the respiratory symptoms had completely overshadowed the digestive disturbances so that the presence of the megacosophagus was almost missed. In 2 cases the symptoms of esophageal disease were established only after re-investigation. The third case, even after the condition was recognized would

not admit symptoms which would make the examiner suspect esophageal disease. For this reason it is important that during the cursory roentgen examination of the chest in such cases, certain signs be found which direct the attention to the possible involvement of the esophagus so that a supplemental contrast medium study of the latter is undertaken. The author enumerates several roentgenographic and roentgenoscopic findings as of very definite help. The enlarged esophagus produces a widening of the mediastinal shadow toward the right side extending from the base of the neck to the diaphragm. The shadow of the esophagus may simulate the right border of the heart which gives the impression of an enlargement of the right side of the heart. Tendency toward pouch formation may result in a scalloped or lobulated sometimes bizarre appearance of the mediastinal shadow. In the presence of numerous small gas bubbles the mediastinal shadow may appear mottled and occasionally there is a fluid level. In the lateral view a forward displacement of the trachea may be noted. The most helpful sign, however, is the demonstration of a double air column overlying the upper dorsal spine in the posteroanterior view. The central air column represents the trachea which is seen through the air column of the upper dilated esophagus.

Whenever any of these findings is present a subsequent contrast medium examination of the esophagus will permit the establishment of the diagnosis of megacosophagus or a differentiation from mediastinal disease and lesions of the spinal column without difficulty.

It is the author's opinion that the pulmonary complications in megacosophagus are the result of aspiration into the bronchial tree of food particles regurgitated from the esophagus into the pharynx as is so often noted in this condition. Pulmonary fibrosis is believed to form a sequela of recurrent aspiration pneumonia, especially since several investigators reported in the literature the isolation from the sputum of such patients of a nonpathogenic, acid fast micro-organism which is identical to that isolated from various fruits and vegetables. If one accepts the occurrence of a pulmonary fibrosis, atelectasis, and pulmonary and bronchial infections as a result of aspiration of esophageal contents, all factors thought to be necessary for the development of bronchiectasis are also present.

Therapeutically the early institution of measures enhancing esophageal emptying so that aspiration of retained contents into the lungs is prevented may be of considerable value.

T. LAUCURIA, M.D.

Taylor J W: Spontaneous Lobectomy *Brit. M. J.*, 1944, 2 500.

It has become increasingly difficult to differentiate between a lung abscess and an empyema. In many

cases the infection is primarily in the lung tissue and invades the pleural cavity only secondarily. This has given rise to the term 'pleuropulmonary abscess'. In the following case the infection was so great that the lung slough of the complete upper lobe became free in an empyema cavity.

The illness began with an attack of lobar pneumonia, which was followed by a period of recovery. This was interrupted by an excessive cough, productive of thick greenish yellow sputum, and accompanied by symptoms of malaise and pyrexia. Clinical examination some two months later suggested an empyema, and drainage was indicated. At this time the cough was noted to be positional, the patient coughed more when he was upright than when flat in bed. The presence of Friedländer's bacillus in the pus from the cavity was a rare and unexpected finding. The skin and subcutaneous tissue in the right upper chest were infiltrated with 0.5 per cent penicillin, and aspiration of the chest in the sixth interspace in the midaxillary line produced pus.

A portion of the sixth rib was removed and the parietal pleura was opened. A large apical cavity was entered and 45 oz. of thick green pus was withdrawn. During a violent fit of coughing a slough of the whole of the right upper lobe was expelled from the wound and followed by a gush of foul-smelling pus. A large drainage tube was inserted into the cavity, the skin was lightly sutured and a light dressing was applied. The lung slough measured 30 by 8 by 6 cm. It had a gray ragged appearance and was pitted with small holes.

Removal of the tube six months after drainage was started still left a cavity in the right upper zone. This cavity was draining into a patent bronchus on its lower and medial aspect. Up to this time the presence of the cavity has not given rise to any symptoms. The question of an apical thoracoplasty must, however, be kept in mind, so that the cavity may be closed completely if it should again give rise to any symptoms.

CHARLES BAROCK, M.D.

Cheale, J. M., and Young, F. H.: The Prognosis after Successful Pneumonectomy. *Lancet* Lond. 1944, 247-254.

Pneumonectomy is being performed with increasing frequency. There has until recently been little dependable evidence on which to estimate the post-operative hospital stay, the time elapsing before patients could resume work, and the capacity for normal life and work.

The authors studied the cases of 25 patients operated upon between 1935 and 1940 who had survived the operation at least once year. The symptom which most often keeps the patient with a surgically successful case from gainful occupation is dyspnea on mild exertion. A simple test was adopted to gauge this factor: the degree of dyspnea produced by walking upstairs from the ground to the first floor of an ordinary house. It was believed that if this could be done without dyspnea the patient could lead a useful life. It is also important to

realize that a bronchial fistula is the determining factor in the length of stay in the hospital and the length of time before work can be resumed.

In the series studied by Cheale and Young the average stay in the hospital was fifteen weeks. In the cases of 13 patients gainfully employed, the average time since operation was eleven months. (When there is no bronchial fistula this period can probably be halved.)

Only 1 patient reported dyspnea at rest—a six-year-old child. On the stairs test 15 reported they were not short of breath, 7 were slightly and 2 were definitely dyspneic. The younger the patient, the less marked was the shortness of breath.

J. M. Mora, M.D.

White, W. L., Burnett, W. E., Bailey, C. P., Rosemond, G. P., and Others: Penicillin in the Prevention of Postoperative Empyema. *J. Am. M. Ass.* 1944, 26-6.

Most attempts to measure the potentialities of a drug in wound infections, whether in terms of prophylaxis or of treatment, suffer from extreme degrees of variations in the lesions studied. The wound variations occur in respect to size, depth, anatomic location, infecting agents, degrees of contamination, types and numbers of organisms present, and the amount of contained foreign matter. Wounds also vary with the individual patient as to age, concomitant disease, nutrition, individual host resistance, and healing capacity. Still another source of variation is the management of the wound, the length of time that has elapsed between injury and definitive treatment, the extent of debridement and of wound closure, the degree of tension in closed wounds, adequacy of immobilization, frequency of dressings, and the duration of hospitalization. In established infection all of these variables are present, plus the factors of bacterial invasion, bacterial toxins, and bacterial symbiosis, which further complicate the picture. Hence, it is considerably more difficult to assess the efficacy of a drug in surgical infections than in the more uniform non-surgical diseases such as pneumonia, cerebrospinal meningitis, or gonorrhea, in which factors relating to the presence of a wound are nonexistent.

This study was designed to minimize the factors of variation, to offer adequate and comparable controls, and to provide a clearly definable end-point as the basis for evaluating the agent. Therefore, the objective of these authors could be simply stated as follows: To determine if penicillin is of value in the prevention of empyema following transection of the bronchi.

The effect of penicillin as a means of preventing postoperative infectious complications after lobectomy and pneumonectomy was so clearly demonstrated in 40 experimental and control cases that it was not believed justifiable to continue the use of controls. The frequency of hemolytic streptococcal empyema in control cases probably accounts for much of the success obtained with the use of sul-

foamades in recent years. The occurrence of post operative empyema in all control cases of lobectomy pneumonectomy, and bronchiectatic and lung abscess is very striking when compared with the absence of postoperative infection in the cases receiving penicillin.

The preoperative administration of penicillin has been a most important feature of this study. The drug given during this period probably serves to control acute and chronic infection in the pulmonary tissues, which reduces the possibilities of postoperative infections. In addition the preoperative use of penicillin affords a maximum therapeutic effect at the time the pleural space is exposed to bronchial contamination.

Penicillin administered by intramuscular injection for one week preoperatively and two weeks post operatively in doses of 150,000 units daily appears to be useful in preventing postoperative pyogenic infections following lobectomy or pneumonectomy.

Penicillin is apparently of no value in preventing or controlling tuberculous infections.

JONAS E. KIRKPATRICK, M.D.

ESOPHAGUS AND MEDIASTINUM

Ladd W. E., and Scott H. W. Jr.: Esophageal Duplications or Mediastinal Cysts of Enteric Origin. *Surgery* 1944, 16: 815.

The authors report 5 cases of mediastinal cysts of enteric origin from the Children's Hospital of Boston, Massachusetts. These cysts are more properly called "esophageal duplication" since they actually arise from or are adherent to, the esophagus. In 4 of the 5 cases, the muscularis layer of the esophagus may be continuous with the wall of the cyst. In 1 of the cases, however, no attachment to the esophagus was found.

These enteric duplications are found early in life, the youngest patient being three weeks of age and the oldest twenty-two months of age. The oldest recorded patient in the literature was a boy three and one-half years of age. Both sexes are equally involved.

The symptoms caused by these duplications are those of an enlarging mediastinal mass producing pulmonary or esophageal compression such as cough, dyspnea, cyanosis, recurrent pneumonias, dysphagia or regurgitation of food. Pain may also be a feature, due apparently to increased intracystic pressure. Hematemesis and hemoptysis have both been observed in these patients and is due to the diminution of the blood supply to the bronchial or esophageal mucosa with subsequent sloughing. Peptic ulcer may occur in the mucosal lining of these duplications.

The roentgenological examination shows a mediastinal mass situated posteriorly. It is usually spherical due to the fluid content. The heart and mediastinal structures may be displaced. Bronchograms may show pulmonary compression but no connection with the enteric duplication. Likewise esophageal

examination with contrast media shows no actual fistulous connection between the duplication and the esophagus itself. Occasionally a vertebra or rib may show erosion from pressure.

These cystic structures are of variable size and may be situated anywhere along the entire length of the mediastinum. They expand either into the left or right hemithorax. The walls are rather thick and the lining is mucous membrane. They often have two muscular layers resembling the esophagus. The mucosa may be that of the esophageal or gastric type. No serosa is present but the pleura which overlies the mass may be mistaken for it. These masses are always retropleural. In 4 of 5 of the cases the mass was attached to the esophagus; in fact, it could not be separated from this organ. The layers of the mass may blend with those of the esophagus. No fistulous connection between the mass and the esophagus was found either at operation or at autopsy.

The contents of these cysts resemble the gastric juice and positive reactions for pepsin and rennin may be obtained with tests. In addition, high titers of hydrochloric acid may be encountered.

The various theories regarding the embryological aspects of this anomaly are discussed.

Treatment consists of excision of the mass if possible. It is usually found, however, that the mass cannot be completely removed without serious injury to the esophagus. In fact, it is often a very sessile attachment. If it cannot be completely removed it is marsupialized and packed with gauze or other coarse packing to allow the mucosal lining to slough or some sclerosing solution may be injected into the cyst after marsupialization. Curettage of the exteriorized sac was done in 1 case with satisfactory results and the sinus tract healed and obliterated itself.

Two of the 5 patients observed died but the other 3 recovered. The oldest child has now been followed up for sixteen years and there is no disturbance of the anatomy or physiology of the thorax.

FORREST D. DODGILL, M.D.

MISCELLANEOUS

Ferguson C. F. and Neuhauser E. B. D.: Congenital Absence of the Lung (Agenesis) and Other Anomalies of the Tracheobronchial Tree. *Am J Roentg* 1944, 53: 459.

Only about 50 cases of congenital absence of the lung have been recorded in the medical literature. In 6 of these diagnosis had been made before death.

The authors, during the past six years, observed at the Children's Hospital of Boston, Massachusetts 5 cases of agenesis of the lung, all of which were diagnosed during life by bronchoscopy and lipiodol roentgenography. One of the patients died and autopsy confirmed the clinical diagnosis. The remaining 4 enjoy apparently normal lives.

A review of the literature reveals that agenesis of the lung occurs with preference on the left side and is encountered more frequently in males than in females.

males. In the authors' series the absent lung was found on the left side in 3 cases, but 3 patients of the 5 were females.

Various theories have been propounded to explain this developmental anomaly. Since the condition often is associated with other congenital defects, a developmental error of endogenous origin in the germ plasma constitutes probably the most logical cause. The associated defects, according to the literature include narrowed trachea, extracartilaginous rings, supernumerary bronchi of the normal lung, absence of the pleura on the affected side, tracheo-esophageal fistula, esophageal stenosis, synostosis of various ribs, absent diaphragm on the affected side, atresia of the anus, hypoplasia of the face, absence of one ovary and tube, agenesis of the spleen, kidney and ureter, exencephaly and absent vagus nerve. Each of the authors' 5 patients had some other anomaly such as harelip and cleft palate, absent hand and wrist on the affected side, defect of the external ear and other minor congenital defects.

Schneider differentiates 3 anatomic subdivisions of agenesis of the lung: (1) true aplasia, cases in which there is no trace of a lung, bronchus, or vascular supply on the affected side, (2) cases in which there is a primordial bronchial bud but no lung tissue and (3) extreme hypoplasia, cases in which the bronchus is fully developed, but reduced in size and ending in a fleshy structure without lobes which lies in the mediastinum. Two of the authors' 5 cases belonged to group 1 and 3 to group 2. The third group is very rare, only 5 such cases having been reported in the entire literature.

No symptoms are noted in many cases of agenesis of the lung and the condition is discovered accidentally as happened in some of the authors' cases during physical examination of otherwise essentially normal children. If however, symptoms are present, they may be very variable and inconsistent. Positive physical signs include diminished respiratory excursion, slight flattening of the thorax with possible scoliosis, dullness or flatness to percussion and absent breath sounds or bronchial breathing. In practically every case, the potentially vacant space is filled with heart, displaced mediastinal contents, or fluid.

The clinical examination very often leads to an erroneous diagnosis of pneumonia, massive atelectasis, foreign body in the bronchus, hydrothorax, diaphragmatic hernia, or diaphragmatic paralysis. However from a roentgen study of the chest the condition may be suspected. There is a dense homogeneous shadow on the affected side with displacement of the heart and mediastinal contents, elevation of the diaphragm, and narrowing of the intercostal spaces. Bronchoscopy is, then, the final method of accurate diagnosis especially if followed by lipiodol injection of the tracheobronchial tree. The authors briefly present the case histories in their 5 patients, accompanied with the respective roentgenograms and bronchograms.

The prognosis is guarded but not incompatible with longevity. The oldest patient in the author's series is over eight years of age. Three of the patients reported in the literature lived well over fifty years.

T. LEVOTINA, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Palmer W. L. and Humphreys E. M.: Gastric Carcinoma. Observations on Peptic Ulceration and Healing. *Gastroenterology* 1944 3 357

Here again is presented evidence that certain ulcerating gastric carcinomas may present the architectural characteristic of peptic ulcer and that such ulcers may in fact heal and the scar be covered by neoplastic mucosa or by a layer of epithelium perfectly normal in appearance.

The first patient, forty years of age, had suffered some months previously with symptoms vaguely suggesting peptic ulcer which had improved under ulcer management and then presented roentgenologically a small penetrating gastric ulcer with maximum (histamine) free acidity of 106. At autopsy two months later a lesion about 1 cm. in diameter and from 1 to 3 mm. deep was found grossly this lesion appeared to be benign. However microscopic examination disclosed frank carcinoma in the mucosa on both sides of the ulcer and growing over the base in some places. Extending laterally from the ulcer into the mucosa was a linear slightly depressed and puckered scar up to 1 cm. wide and 4 cm. long apparently lined with mucosa. In this scar were noted the fusion of muscularis mucosae and muscularis propria and the complete re-epithelialization of a healed ulcer but there were definite neoplastic cells in this epithelium and beneath the muscularis mucosae.

The second patient a male of fifty-six years had shown symptoms (attacks of hematemesis and tarry stools gnawing epigastric pains high free acidity) and x ray evidence of a large penetrating ulcer high on the lesser curvature of the stomach with gas roentgenologically "tremendous hypertrophic gastritis of the whole stomach suggestive of extensive neoplastic infiltration. His condition improved rapidly on ulcer management with a marked decrease in the size of the ulcer as shown roentgenologically. However a year later this ulcer was still present although small and a new ulcer was found in the prepyloric region of the antrum. The latter ulcer disappeared roentgenologically and then reappeared. Autopsy some weeks later disclosed a diffusely infiltrating carcinoma of the stomach with pyloric obstruction, carcinomatous peritonitis, healed gastric ulcer in the prepyloric region and chronic in active ulcer high on the lesser curvature. Three centimeters from the esophageal junction and 15 cm. from the lesser curvature on the posterior wall of the stomach there was a defect in the mucosa 8 mm. in diameter. This ulceration showed a cleanly sloping wall and a firm grayish-white base with considerable scarring and stellate contraction. There was another irregularly depressed scarlike area on the lesser curvature about 3 cm. from the pylorus.

The architecture of the ulcer high on the lesser curvature and the high gastric free acidity again may both be interpreted as evidence in favor of the initial benign nature of the lesion although the course speaks strongly against this view. The ulcer disappeared and recurred but at autopsy it was found to be healed. Here as in case 1 the regenerated mucosa contained neoplastic cells.

Case 3 was that of a carpenter seventy-one years of age, with a low free acidity (26 with histidine) but otherwise with a rather typical ulcer history for about three years. Occult blood (benzidine test) was persistently present in the feces in varying amounts and roentgenography and gastroscopy disclosed a "craterlike big ulcer" of the lesser curvature which under ulcer management decreased markedly in size while the occult blood persisted but later the ulcer increased in size again and in the resected specimen it was found to be 10 by 15 mm. in diameter surrounded by an edematous hyperemic mucosa which was microscopically adenocarcinoma.

Case 4 was that of an unmarried female forty-one years of age, who had been suffering for about two years with pain of the ulcer type which was relieved by eating and by taking soda. Roentgenography disclosed a crater on the lesser curvature with radiating polypoid folds and a tendency toward annular constriction of the antrum. Two months later under ulcer management the ulcer had disappeared roentgenologically but the abnormality of the wall was still evident. However a month later the crater was again faintly visible and although it was decreasing progressively in size it was always visible gastroscopically surrounded by a stiff infiltrated nodular area. When the resected specimen of stomach was opened there was disclosed an area on the lesser curvature from which the mucosal folds radiated outward. The lesion was firm, not hard and the borders were very slightly raised. At the center were two small ulcerated areas each measuring 1.0 by 0.6 cm. by 1 mm. deep, with a smooth floor. The remainder of the lesion was covered by soft pink tissue similar to but slightly pinker than the surrounding mucosa. In spite of the two-year story of periodic distress of the ulcer type there was nothing pathological to suggest the previous existence of a benign peptic ulcer. There was on the other hand evidence of peptic ulceration in a neoplasm and of subsequent healing with a layer of normal-appearing well polarized simple epithelial cells covering fresh granulation tissue and the underlying tumor.

Excellent photographs accompany the article.

In the discussion EUSTERMANN of Rochester, Minnesota states that about 10 per cent of gastric carcinomas masquerade as benign gastric ulcer and that some carcinomatous lesions occasionally respond to treatment so favorably that their malignant nature is not suspected.

FITZGIBBON of Portland Oregon reports a gastroscopically diagnosed gastric ulcer which under ulcer management at the end of one and one-half months was healed and completely covered with mucosa, with the puckered appearance that one might expect from a scar. Later however it exhibited gastroscopically an extensive carcinomatous involvement. At operation involvement of the posterior wall and lesser curvature with lymph node and liver metastases was found.

CROWN of New York says that he did not realize, until he heard Palmer speak, that a malignant ulcer might "heal" and become covered by epithelium. However the healed malignancy is covered not by a normal epithelium, but by malignant carcinomatous epithelium. The malignant ulcer never heals completely.

RUFFIN of Durham, N. C. asked the speaker if he subscribes to the aphorism "Carcinomas may ulcerate but ulcers do not carcinoma." Palmer replied in the affirmative. JOHN W. BRIDGMAN, M.D.

ILLINGWORTH, C. F. W., SCOTT, L. D. W., and JAMIESON, R. A. Acute Perforated Ulcer in the West of Scotland. *Brit. M. J.* 1944 67

To ascertain the incidence of perforated ulcer in the twenty year period from 1924 to 1943 records were obtained from the three main Glasgow voluntary hospitals the Royal, Western and Victoria Infirmaries. The number of perforations treated annually increased rapidly in the period under review. In the prewar years there was a fairly uniform increase from rather less than 200 in 1924 to rather more than 400 in 1938. During the war the number of perforations was higher in 1940 and 1941 and lower in 1942 and 1943 than would have been expected on the basis of the trend in the previous sixteen years both the excess and the deficiency are statistically significant. It should be added that these changes are not due to wartime changes in the population. The incidence of perforation per 100,000 from 1924 to 1938 follows:

Year	1924	25	26	27	28	29	30	
Incidence								
Per 100,000	11	12	16	17	19	20	19	
Year	193	32	33	34	35	36	37	38
Incidence								
Per 100,000	20	30	19	23	22	22	25	

The author reviewed the incidence of perforations during the present war with special reference to air raids. In London the rising incidence was noted shortly after serious air raids began (in September, 1940) and a similar correlation was noted in Bristol and Liverpool. So far as Glasgow is concerned however a close study of the figures leads to the conclusion that such a correlation did not exist. In Glasgow the incidence rate began to rise in the autumn of 1940 reached a high peak in March 1941 and remained abnormally high until the end of June, 1941. However in Glasgow the rise in incidence did not follow air raids on the contrary it anticipated them. In Glasgow there was nothing comparable to

the prolonged bombardment to which London was subjected. Apart from a few desultory raids, which excited greater interest than apprehension, the first attacks to be sustained were the two heavy raids in March, 1941. These raids occurred on March 13 and 14 and March 14 and 15 but the high incidence of perforations in March cannot be attributed to them, for of the 86 perforations recorded in March no fewer than 41 occurred before the air raids began. From these observations it is clear that in Glasgow the local air raids cannot be held responsible for the 1940 and 1941 increase of perforations and other factors must be considered. During the period in question the whole country was in a state of nervous strain as a result of the war situation. From the summer of 1940 onward, also there was a great increase in the amount of overtime work, and there were additional duties in connection with the Civilian Defence Services and the Home Guard the resulting weariness, lack of sleep, and irregularity of meal hours might well be tolerated for a few months but might later precipitate perforation. Finally it is possible that the food shortage which was beginning to be evident at that time may have exerted an influence. The fall of incidence after June 1941 and in 1942 and 1943 is equally interesting and even more difficult to explain. It could be suggested that ulcer patients who might have experienced perforation in 1942 or 1943 had already done so in 1941 but this explanation will not do for one perforation does not protect against subsequent ones. There is indeed no ready explanation of this fall in incidence.

In sex distribution a great preponderance of males is evident and the overall ratio of males to females is 6,796 to 360 or 19 to 1. The incidence rate of perforations increased in both sexes throughout the twenty year period, and the ratio of 19 to 1 was substantially maintained although there were wide fluctuations from year to year. The rise in 1940 and 1941 and the fall in 1942 and 1943 were confined to males. In females the general trend of the prewar years was maintained. This finding is somewhat surprising in view of the great changes which have taken place in the habits and working conditions of women, especially since 1930.

The general characteristics of the age distribution showed that the incidence reaches its maximum in patients between thirty-five and forty five years of age and falls only slowly in older patients. An interesting feature was the sudden increase in the frequency of perforation at adolescence. Perforation in childhood is rare. There was 1 perforation at eight years, 1 at eleven and 1 at twelve years. From age thirteen to nineteen there is a truly remarkable increase, the numbers observed at the successive single years of age being 1, 6, 6, 32, 44, 86, 101. The age distribution did not remain stable throughout the period. Between 1924 and 1933 the mean age rose by some three and one-half years, the rate of increase being fairly uniform. The rise was doubtless due in part to the increasing mean age of the popu-

lation in the area served. There was a small but nevertheless real difference in age incidence in the two sexes.

CHARLES BARON M.D.

Mingworth, C. F. W. Scott, L. D. W. and Jamieson, R. A.: Acute Perforated Peptic Ulcer in the West of Scotland. *Brit. M. J.* 1944, 2: 655

The authors have reported figures relating to the incidence of perforated peptic ulcer over a twenty year period in an area of western Scotland with a population of over two million inhabitants.

From 1924 to 1938 there was a progressive increase in the incidence of perforations. During the period of the war this steady increase has been interrupted by a marked rise during 1940 and 1941 followed by a return to a lower level. These changes concern duodenal ulcer almost entirely the incidence of which far exceeded that of all other types of ulcer. The total number of cases was 3,882. Of these 493 (12.7 per cent) were gastric ulcers, 3,220 (82.95 per cent) were pyloroduodenal ulcers, 52 (1.34 per cent) were anastomotic ulcers, the location of 117 (3.01 per cent) was not stated. The rise in incidence during 1940 and 1941 was not correlated with air raids in this part of the country but it is suggested that in addition to anxiety about the war situation, overwork and perhaps undernutrition may have exerted some influence.

The sex ratio has undergone little change during the twenty year period. The rise of incidence in 1940 and 1941 and the fall in 1942 and 1943 were confined to men. In women the general prewar trend was maintained during the years of war. This finding is somewhat surprising in view of the great changes that have taken place since 1939 in the habits and working conditions of women. There is a predominance in males of perforations of all types. The sex difference is particularly striking in anastomotic ulcers, all of which occurred in males. There is a difference in the sex ratio of gastric and duodenal perforations. In males, 12 per cent of perforations were gastric and 83.6 per cent were duodenal the comparable figures for females were 25 per cent and 70.6 per cent. Statistical analysis shows that it is highly improbable that the difference in sex ratio has arisen just as a matter of chance.

Perforation occurs rarely during childhood its incidence rises rapidly in adolescence and attains a maximum between the ages of thirty and forty years. Since 1924, there has been a rise in the mean age which does not appear to be due entirely to aging of the population. The mean age is higher in females than in males.

Perforations are unduly common in the month of December and relatively uncommon in the months of August, September and October. This low incidence in the summer months may possibly have a nutritional basis, or may be related in some way to the summer holiday season. Perforations occur less frequently on Sundays and Mondays than on other days, and this may be related to rest over the week end. Perforations are unduly common between the

hours of three and six o'clock in the afternoon and comparatively uncommon during the night and morning. The relation of these phases to meal times is not clear and requires further study. There may be a correlation with periods of stress and rest respectively.

The fatality rate from perforation increases with age and with delay in treatment. It is greater in gastric ulcer than in duodenal ulcer in females than in males, and in winter than in summer. The last may well be attributable to the increased risk of pulmonary complications in the winter months.

CHARLES BARON M.D.

Warren R. F. Primary Malignant Tumors of the Small Bowel. *Cases of Am. J.* 1944, 51: 451

Although primary malignant neoplasms of the gastrointestinal tract are extremely common there is a surprising variation in their incidence between the pylorus and the ileocecal valve. The author presents 26 cases as follows:

Adenocarcinoma in the first part of the duodenum	0
Adenocarcinoma in the second part of the duodenum	4
Adenocarcinoma in the third part of the duodenum	1
Adenocarcinoma in the duodenojejunal junction and jejunum	11
Adenocarcinoma in the ileum	1
Total	17
Sarcomas	4
Carcinoids	4
Primary Hodgkin's disease of the small bowel	1
Total	26

The series supports the claim that duodenal malignant disease tends to occur most frequently in the periampullary region. The onset of a painless jaundice which is said to characterize malignant change was seen in only 1 case. Three of the 4 patients gave a history of a year or more of gastrointestinal upsets which were suggestive of ulcer or cholelithic indigestion.

Adenocarcinoma of the small intestine exclusive of the duodenum is said to make up 3 per cent of intestinal cancers according to Ewing. This suggests a slightly greater frequency of duodenal cancers than of jejunoileal cancers. This is not borne out by the author's series in which the ratio is 5 to 12.

Carcinomas tend to develop at the extreme upper and lower ends of the small bowel and leave the central portions free. This was shown in this series by the occurrence of 11 carcinomas in the jejunum or duodenojejunal junction, and 1 in the terminal ileum.

Less common than adenocarcinoma is sarcoma, which is found more often in the small than in the large bowel. This series included 4 cases about 14 per cent of the total made up of 1 sarcoma of uncertain cell type, 1 reticulum-cell sarcoma, 1 malignant melanoma and 1 leiomyosarcoma. All 4 cases in

volved the ileum and thus conformed to the accepted view that sarcomas of the small bowel occur most frequently in the ileum.

Four carcinoid tumors or 14 per cent of the total series are reported. Usually these arise in the appendix and may not be recognized at the time of operation. Nevertheless they occur with considerable frequency in the small bowel usually the ileum and have been reported in the stomach and colon. Were it not for incidental cases picked up at routine autopsy few if any of these not infrequent tumors would be discovered.

Finally, 1 case of Hodgkin's disease of the small bowel was included.

The 17 cases of adenocarcinoma were divided equally between the sexes. The age incidence for the males was sixty and eight-tenths years, while that of the females was fifty three and five-tenths years.

The symptoms in many cases were of long standing. One patient had twenty years and another twenty seven years of gastrointestinal upsets. Symptoms are nearly always referable to mechanical obstruction. The tumor may be one of three types (1) that which engirdles and strangles the bowel (2) that which by its fungating massive growth obstructs the lumen, and (3) that which by a process of low infiltration finally brings about stricture of the lumen. Pain is not characteristic until obstruction supervenes. The symptoms may be divided into those of long-standing irritation and those of the acute obstructive phase. Occasionally there are tarry or bloody stools. The obstructive phase includes nausea and vomiting, jaundice (especially in carcinoma of the second part of the duodenum), loss of weight, loss of appetite, and increasing constipation.

The prognosis is poor. There are usually metastases when the patients are admitted. 11 of the 17 in this series had metastases and 9 died in the hospital. Of those that left the hospital 5 died within two years. For carcinoid tumors the outlook is much brighter. The rarer sites for these tumors are known to signify more malignant cases.

STEPHEN A. ZEEMAN, M.D.

Shallow T. A., Eger S. A. and Carty J. B.: Primary Carcinoma of the Third Portion of the Duodenum. *Surgery* 1944, 6: 939.

Primary carcinoma of the small intestine is a comparatively rare lesion and extremely so when in the third portion of the duodenum. Since an opportunity seldom arises for radical resection of such a lesion, there being only 12 unquestionable cases reported, the authors describe a case in which a new operative procedure was successfully employed its advantages are discussed, and details of the other resected cases are tabulated.

A sixty-three year-old white man had been in excellent health until one year prior to admission to the hospital, when epigastric fullness occurred about one half to one hour after meals, and remained for several hours unless relieved by belching. No par-

Fig. 1. Anatomic relationship of tumor represented diagrammatically. Lines A and B are sites of resection.

ticular type of food brought on an attack, which occurred every four to six weeks at the onset but gradually increased in frequency and severity. For two weeks prior to admission epigastric distress and fullness were constant, and were relieved only by vomiting. The vomitus was bile stained and contained particles of food ingested several meals previously but it never contained blood. There was a loss in weight of 20 pounds during the last six months, and most of this occurred in the last two weeks.

Abnormal findings consisted of mild dehydration, moderate epigastric distention and a deep, firm, fixed nontender mass 3 inches in diameter just above the umbilicus. The gastric contents contained a residual total acidity of 35 and free hydrochloric acidity of 20. After a test meal these figures gradually rose to a maximum of 48 and 27 respectively, in the sixth specimen. There was bile present in all the specimens but blood and lactic acid were absent.

Röntgenographic study of the gastrointestinal tract demonstrated almost complete obstruction at the beginning of the ascending loop of the duodenum. The diagnosis made was a lesion in the third portion of the duodenum probably due to a malignancy either primary or secondary.

After the patient was transferred to the surgical service operation was performed on August 4, 1943. A tumor was found involving the posterolateral wall of the third portion of the duodenum beneath the superior mesenteric vessels. The adjacent retroperitoneal tissue was indurated, but there was no evidence of extension of the growth or metastases. The entire third portion of the duodenum was mobilized and resected. The free ends of the bowel were closed. An antecolic duodenojejunostomy was performed in a side-to-side manner to anastomose the jejunum, about 10 inches from the ligament of Treitz, to the second portion of the duodenum, just

Fig. 1. Third portion of duodenum and duodenojejunal angle mobilized prior to resection. Dotted line on second portion of duodenum represents site for side-to-side duodenojejunostomy.

distal to the ampulla of Vater. The suture line of the closed duodenal stump was reinforced by anchoring it to the posterior surface of the jejunum just distal to the anastomosis. The jejunal stump was attached to the ligament of Treitz to leave the proximal jejunum available for a gastroenterostomy should the duodenojejunostomy stoma have proved inadequate. The abdomen was closed without drainage.

The histological diagnosis was primary ulcerative adenocarcinoma of the duodenum. Nine months after operation the patient was symptom-free, had gained 30 pounds in weight, and x ray examination following a barium meal revealed no kind of abnormality.

The authors have been able to collect from the world literature reports of only 12 unquestionable cases of primary carcinoma of the third portion of the duodenum in which resection was done. The procedure employed by the authors has the following advantages:

1. The anastomosis is safer for it is performed where the duodenum has a peritoneal covering.
2. The closed duodenal stump is reinforced by being buried in the under surface of the distal jejunal loop.
3. With the side-to-side anastomosis the angles can be well fortified and the size of the stoma regulated without encroachment on the common bile duct, ampulla of Vater or the blood supply of the remaining duodenum.
4. With the jejunum antecolic, obstruction from pressure by the superior mesenteric vessels and from the passage through the transverse mesocolon is avoided.
5. A proximal jejunal loop is provided for a gastrojejunostomy should the duodenojejunostomy stoma prove to be inadequate.

JOSEPH K. NARAT, M.D.

Woods, F. M. and Hanlon, C. R. Inflammatory Stricture of the Rectum: An Analysis of 192 Cases, Including 35 Treated by Rectosigmoid Resection. *Ann. Surg.* 1944, 120, 598.

The treatment of inflammatory rectal stricture has long been unsatisfactory. The causal relationship of lymphopathia venereum to rectal stricture is now generally conceded, but there is no such unanimity of opinion regarding treatment. There are many reasons for this difference of opinion.

First, the strictures vary from simple fibrous narrowings causing no symptoms to extensive lesions involving the rectum and colon with partial or complete obstruction.

Second the presence of ulcerations, sinuses and fistulas may complicate the problem.

Finally the degree of co-operation of the patient will determine management. Measures involving repeated clinic visits, prolonged administration of drugs or observance of careful hygiene are generally not employed successfully in such patients as form the bulk of the authors' practice.

The various modes of attack on inflammatory rectal stricture may be grouped conveniently under four headings: (1) drugs and antigens, (2) irradiation, (3) dilatation and (4) surgery.

With asymptomatic stricture, insistence on careful hygiene and regulation of the bowels may be sufficient. Patients have been followed for as long as twenty years in this series without appreciable progression of symptoms.

With strictures showing evidence of inflammatory activity or intestinal obstruction, more active treatment is necessary.

This may consist of sulfonamides with which good results have been reported both in the early stages of the disease and in secondary infections. The authors have not seen the resolution of firm fibrous strictures as reported by some authors.

Antigen therapy has been recommended for all forms of the disease but published reports offer little encouragement for treatment of rectal stricture by this method. The authors' experience with antigen therapy has been negligible.

Dilatation has been widely used. It affords temporary relief of obstructive symptoms in the great majority of patients although the risk of exacerbating the infection or perforating the bowel is commonly recognized. The authors' experience includes 7 deaths attributable to this procedure.

With an inflammatory rectal stricture that does not respond to conservative measures, colectomy may be expected to eliminate obstruction and in many patients to mitigate the inflammatory symptoms. Forty-one per cent of the authors' patients were benefited by simple colectomy. In comparing this result with that in the resected cases of which 94 per cent were improved, one should recall that a higher percentage of 'severe' cases were subjected to simple colectomy. This may account partially for the 'poor' results in the latter group.

Several authors have reported radical removal of the diseased rectosigmoid usually by perineal resec-

tion. Failures following this operation may be attributed to extension of the disease beyond reach of the perineal approach. The only "poor" results in this series of resections occurred with the perineal approach because of persistent drainage from the perineum or from the distal colostomy loop. Twenty-three combined abdominoperineal resections of which 16 were in one stage, gave quite satisfactory results. Certain of these cases might have been managed with equal success by less radical methods. In the majority, however, the rapid restoration of the chronically ill patient to good health apparently justified such drastic treatment.

JOSEPH GASTEL, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Berman C.: The Clinical Features of Primary Carcinoma of the Liver. *Clin. Proc., Cape T* 1944 3 333

Primary carcinoma of the liver is a problem of major importance to South African medicine, because it occurs with appalling frequency in most pigmented races. In Europe however it is one of the rarest of tumors. Among the Bantu and Javanese males, particularly it is undoubtedly the most frequent form of carcinoma. While the postmortem rate is 0.13 per cent in Europe and 0.25 per cent in America among Asiatic races it is 1.3 per cent for the Javanese, 1.21 per cent for the Japanese, 1.9 per cent for the Chinese, and 1.44 per cent for the Philippine Islanders. For the African Bantu it is 1.2 per cent. Again, while the percentage frequency of primary liver cancer to all other forms of cancer is 1:1 per cent in Europeans and 2:1 per cent in Americans, it is 36:3 per cent in the Javanese, 36:1 per cent in the Chinese, 2:1 per cent in the Philippine Islanders, 7.8 per cent in the Japanese and 25.3 per cent in the Bantu.

There are no symptoms which are pathognomonic of primary carcinoma of the liver. Nevertheless, if the clinical manifestations are taken collectively ample evidence is furnished from which a correct diagnosis can be made. Primary liver cancer is predominantly a disease of males. In the Bantu it occurs chiefly in young adults. Elsewhere, however it is commonest in or after middle age. Cirrhosis occurs with such regular frequency in primary liver cancer that many pathologists regard it as an intermediate stage in the neoplastic evolution, especially as numerous known cirrhotic agents have frequently been discovered in close association with liver cancer. Among these are intestinal parasites, malaria, schistosomiasis, distomatiasis, echinococcus infestation, and hemochromatosis.

Since Sasaki and Yoshida first produced primary liver cancer in rats by feeding them with the hydrocarbon α -aminonaphthalene no organ has yielded more spectacular results in the experimental production of cancer than the liver. Other related chemical compounds, like p -dimethylaminonaphthalene (but

ter yellow) are today producing liver cancer with even greater ease.

A study of 66 Bantu cases of primary liver cancer has indicated that the clinical course of the disease is by no means uniform. The symptomatology is dependent upon the rate of neoplastic growth, complications, and metastases. Accordingly, the author has divided his cases into five clinical groups as follows: (1) frank cancer i.e. with symptoms of primary liver involvement (63.6 per cent of cases) (2) acute abdominal cancer i.e. with symptoms associated with an acute abdominal catastrophe (9.1 per cent) (3) febrile cancer i.e., with fever as the salient clinical feature (7.6 per cent) (4) occult cancer, in which malignancy is discovered accidentally (15.1 per cent) and (5) metastatic cancer with symptoms referable to the organs involved by metastases rather than to the liver (4.6 per cent of cases).

The diagnosis is based upon clinical findings together with microscopic examination of pathological material obtained at operation or biopsy. Roentgenological examination is of value in suspected "metastatic" cancer. Verification of the diagnosis, however is often established only at autopsy. All liver function tests devised thus far including the galactose test and the bromsulphalein test are of doubtful value. Recent work has indicated however, that the Takata-Ara test may be of value in the diagnosis. This is a flocculation test of serum with a mixture of sodium carbonate and mercuric chloride.

The following diseases must be considered in the differential diagnosis.

In frank primary liver cancer—neoplasms of the pylorus, transverse colon, pancreas or right kidney including their metastases to the liver; cirrhosis, syphilis, chronic venous congestion, or cystic disease of the liver; cholelithiasis, abdominal tuberculosis, leucemia, Banti's disease and amyloid disease.

In acute abdominal cancer—volvulus of the small intestine, perforated gastric, duodenal or umbilical typhoid ulcer, ruptured liver or spleen, biliary or renal colic, acute appendicitis, acute pancreatitis and mesenteric thrombosis.

In febrile cancer—abscess, liver abscess, intrahepatic suppuration, hydatid cyst of the liver, malaria, and subphrenic abscess.

The outlook is hopeless as the disease is rapidly fatal. Indications of approaching death are sudden marked enlargement of the liver, rapidly intensifying jaundice, increased dilatation of the superficial abdominal veins and additional edema of the extremities.

Because of the hopelessness of the disease, treatment is essentially palliative and is directed toward the relief of pain and discomfort. Sedatives are always required in large and increasingly frequent doses. The question of surgical treatment must be considered. In the author's own cases, however all attempts at radical cure had to be abandoned on account of metastases in other parts of the liver. Reports in the literature, too, indicate that operative

results have been very poor. It is possible that x-ray and radium therapy may prove of value in treatment. The author has been unable to study the effects of these methods because of the lack of facilities.

JOSEPH K. NARAY, M.D.

Brush, B. E. and McClure, R. D.: Hyperinsulinism Treated by Subtotal Pancreatectomy. *Iowa Surg.* 1944 120-750.

Functional hypoglycemia is fairly common but organic hyperinsulinism is rather rare. It is of utmost importance to study every diagnostic aid available in order to establish an etiological diagnosis of hypoglycemia.

The Whipple triad of symptoms is a definite indication for surgical exploration of the pancreas. An islet tumor will be present in nearly all of the cases. The Whipple triad includes (1) disorders of the nervous system such as confusion, coma, convulsions collapse coming on in the fasting state; (2) a drop in the blood sugar level to 50 mgm. per 100 cc. or less; and (3) the relief of symptoms brought about by the administration of glucose. Blood sugar above 50 mgm. per 100 cc. during an attack points to other causes than islet adenoma. The etiological factors may be found in Table I.

Also under these circumstances a diet low in carbohydrate (50 gm. or less) and high in protein often gives relief from attacks. This is due to the fact that while 50 per cent of the protein may yield dextrose the slow even rate of conversion, as well as the slower absorption rate of protein, prevent marked elevation of the blood sugar which would in turn stimulate the pancreas. The glucose tolerance curve is influenced by the antecedent diet in normal people as well as in those with hypoglycemia. A glucose tolerance test taken after a proper preparatory diet has definite diagnostic value in hypoglycemia. Both organic and functional hyperinsulinisms characteristically give a low dextrose tolerance curve, and the organic type usually has an abnormally low fasting level. In borderline cases studies on the utilization of injected glucose are indicated. The authors take the basal metabolic rate prior to the injection of glucose, and repeat this test at one-half hour, one hour, two and one-half hours and three hours after the injection. Urine examinations are made for nitrogen and sugar if the proportion of carbohydrate, fat, and protein utilized is to be determined. The calculation of the respiratory quotient gives diagnostic information and is of benefit also in following the patients postoperatively. In patients not conforming to the "Whipple triad" and yet presenting the symptoms of hyperinsulinism these studies may aid in determining the advisability of performing a subtotal pancreatectomy.

Two cases are presented which were characterized by the syndrome of spontaneous hypoglycemia, and the fact that no islet tumor could be found. The results obtained following subtotal resection of the pancreas in these cases were very satisfactory. The study of the metabolism of glucose in these patients after

they had been on a standard preparatory diet, was of benefit in a diagnostic way and also in evaluating the results of treatment. The authors have indicated the results of the preoperative and postoperative glucose tolerance tests and the phosphorus curves in both of their patients by a series of charts. One of the cases required very extensive pre- and postoperative studies.

The first patient was a white, single, female, nineteen years of age. On April 11, 1935 her complaints were severe headache, abdominal cramps, chronic cough and an excessive gain in weight. Roentgenograms of the chest and skull were negative. The basal metabolic rate was -5. The patient was taking 1 gr. of thyroid daily. The fasting blood sugars were 78 and 99 mgm. per cent.

In January 1936 frequent attacks of weakness, sweating, tremor and a stuporous mental reaction were noted. Lack of food induced these conditions, and ingestion of carbohydrates brought quick relief. The blood sugar levels taken during the attacks were from 35 to 60 mgm. The usual routine laboratory examinations were negative. The clinical diagnosis was spontaneous hypoglycemia. At operation approximately two-thirds of the pancreas was removed. During the operation the patient was given 400 cc. of glucose and 500 cc. of whole blood intravenously. Postoperative blood-sugar determinations were made hourly and measured 250, 230, 230, 170 and 140 mgm. per cent, respectively. Fasting

blood-sugar determinations were made daily and measured 135, 129, 111, 129, 105, 91, 75, 93, 96, 84, and 89 respectively. The postoperative course was uneventful; the patient remained asymptomatic, blood-sugar tests taken each year have remained normal.

The gland tissue excised was normal.

The second case presents a more complicated picture. The patient was white, female, age forty-three. The first complaints were of nervousness, backache, low blood pressure, and sinus trouble. The first attacks of nervousness in 1929 were characterized by weakness, irritability, excessive perspiration, and ravenous hunger all occurring about three hours after meals and being worse after exercise; they were relieved by eating, especially readily available carbohydrates. There was a gradual loss in weight. The attacks became progressively more severe and further symptomatology included memory loss during the attacks, mental cloudiness, speech difficulty and visual disturbances but no loss of consciousness. Physical examination was essentially normal. The usual laboratory tests were negative. The fasting blood sugars varied from 61 to 69 mgm. per cent. Roentgenograms of the spine, skull, chest, gall bladder, stomach and duodenum were normal. Severe symptoms were induced in the fasting state by strenuous exertion at which time the blood sugar measured 60 mgm. per cent. One milligram of epinephrine was given subcutaneously with relief of all the symptoms within fifteen minutes, when another blood-sugar specimen measured 73 mgm. per cent.

The patient at this time was discharged on a high protein, low carbohydrate diet, with 5 to 6 meals daily and thyroid extract (1/4 gr.) daily. Symptoms became gradually more severe and the patient was again admitted to the hospital on two different occasions about three months apart. Glucose-tolerance tests were again made on each of these occasions, and the last one had to be terminated at the end of one and three-fourths hours because of the severity of the hypoglycemic reaction. Further laboratory tests were made. The blood nonprotein nitrogen measured 26.5 mgm. per cent, the blood sodium 33; the blood potassium 17.5. The basal metabolism rate was now +4, and the respiratory quotient 0.80.

The patient was given 500 cc. of 10 per cent glucose intravenously in preparation for the operation. In one and one-half hours a reaction occurred which required the injection of 50 cc. of 50 per cent glucose for relief. During the operation 500 cc. of 10 per cent glucose and 500 cc. of whole blood were given intravenously. Approximately five-sixths of the pancreas was resected, but no adenoma was found. Postoperative blood-sugar determinations were made hourly and measured 108, 91, 85, 109, 127, 131, 145, 112, 132 and 98, respectively. The daily blood sugar varied between 80 and 100 mgm. per cent. The postoperative course was completely uneventful with the patient returning to excellent health. The fasting blood-sugar level has been between 80 and 90 mgm. per cent since the operation.

In both cases the microscopic appearance of the pancreas was normal and no islet adenoma was found. The excellent results following subtotal pancreatectomy have led the authors to recommend this as a procedure of choice when no adenoma can be found after a careful search of the pancreas and the usual sites where heterotopic pancreatic tissue sometimes occurs. A large amount of pancreas must be resected in these cases. The function which the pancreas plays in the digestion was not affected significantly when four-fifths of the gland had been removed. Neither were there any metabolic disturbances.

The authors prescribe a high protein, low carbohydrate diet for preoperative trial. They have experienced difficulty in getting patients to refrain from the ingestion of some carbohydrate when the unpleasant prodromal symptoms appeared. The patients' complete confidence is necessary to keep them from escaping this by taking a little carbohydrate, which they have found relieves them, at least temporarily.

The authors point out that hyperplasia of the islet cells is difficult to be sure of pathologically, just as it is difficult to tell which tumors are benign and which are malignant. Especially is this true since the microscopic appearance of the gland in both cases reported was described as normal.

MISCELLANEOUS

Senger, F. L., and Bottone, J. J.: Perirenal Insufflation. *Am. J. Surg.* 1944, 66: 3.

Perirenal insufflation has proved to be of great value in the differential diagnosis of all retroperitoneal lesions in and about the kidney. Its use permits conclusions concerning the local spread and operability of renal tumors. The technique is not difficult, and can be mastered easily. Complications are infrequent, and are of only minor degree, if ordinary care is taken.

A series of 175 consecutive cases in which perirenal insufflation was done is presented; no serious mishap occurred. In all instances added valuable information was obtained. The method should be employed in all indicated cases, although its indiscriminate use is discouraged. No elaborate or expensive equipment is necessary.

SAMUEL KARY, M.D.

Gisgett, O. T., and Tinney, W. S.: Subphrenic Abscess, with Special Reference to Intrathoracic Complications. *Am. J. Surg.* 1944, 66: 89.

Subphrenic abscess can occur after any abdominal operation or any inflammatory process in the abdomen. Too often it is not recognized until serious thoracic complications have developed. Thoracic complications, which are late complications of subphrenic abscess, are responsible for the high mortality rate of this condition. Early recognition and treatment of subphrenic abscess will prevent thoracic complications.

The diagnosis is not difficult in most instances. A history of an abdominal condition which could cause a subphrenic abscess, with evidence of a suppurative process manifested by fever and elevation of the leucocyte count, which cannot be accounted for otherwise, is sufficient to warrant investigation. Anteroposterior and lateral roentgenographic views of the diaphragm with the patient in the erect position are of greatest value. The presence of a fluid level under the diaphragm was demonstrated in this manner in about 25 per cent of the authors' cases. Marked elevation and immobility of the diaphragm are significant. It is generally agreed that diagnostic aspiration should never be attempted in cases of suspected subphrenic abscess. The subphrenic region is not anatomically suited to such procedures as it is necessary to traverse either the peritoneal or pleural cavities with the needle in such cases and the danger of setting up infection in these cavities is very great. Furthermore failure to obtain fluid proves nothing. Exploratory operation is without question the logical and safe procedure in cases of suspected subphrenic abscess.

The extracorporeal approach to subphrenic abscesses is the safest and most effective means of treating them.

The approach to abscesses situated anteriorly as indicated by the lateral roentgenogram is made by an incision just below the costal arch. The incision is carried down through the muscle and posterior fascia to the peritoneum. A line of cleavage is estab-

lished just outside of the peritoneum and by blunt dissection the peritoneum is stripped from the under surface of the diaphragm until the induration and fluctuation of the abscess are demonstrated. An opening is then made into the abscess sufficiently large to establish adequate drainage.

For abscesses situated posteriorly it is necessary to resect the twelfth rib. Meinkoff has demonstrated that in about 62 per cent of cases the pleura extends to the twelfth rib but it never extends as low as the spine of the first lumbar vertebra; therefore a transverse incision is made across the posterior bed of the twelfth rib at the level of the first lumbar spine and, by blunt dissection, a line of cleavage is established below the diaphragm but outside of the fascia enclosing the kidney and adrenal glands, and the dissection is extended until the abscess is reached.

These approaches can be carried out quickly and easily even on patients who are extremely ill. After the establishment of adequate external drainage of these subphrenic abscesses rapid improvement takes place, and in cases complicated by bronchial fistula the fistula closes and the cough clears up rather rapidly. If the bronchial fistula has been present for some time before drainage of the subphrenic abscess is established bronchiectasis may develop in the lung from chronic inflammatory changes in the bronchi, even though the abscess heals satisfactorily. This fact indicates further the importance of early diagnosis and drainage of subphrenic abscess.

GYNECOLOGY

UTERUS

Tribedi, B. P., and Da, S. N.: Observations on Chronic Endometritis. *J. Ind. M. Ass.*, 1944, 13, 30

Two hundred and twenty three pathological specimens were studied with regard to the incidence of chronic endometritis. These were from records accumulated over twenty years in the Pathology Department of the Calcutta Medical College. The study was undertaken because chronic endometritis has been a subject causing considerable confusion.

According to the modern conception, chronic endometritis has the following three characteristic features: (1) it is a rare if not altogether impossible, affection of the endometrium, as the latter does not lend itself to any chronic inflammation because of the simple tubular character of its glands and the regular monthly shedding of its superficial layers in the nonpregnant fertile stage of life; (2) it must be associated with some adjacent nidus of infection in order that the chronic inflammatory condition in the endometrium may be maintained for a prolonged period; and (3) it must exhibit histologically a large number of plasma cells. The presence of these cells in number will differentiate chronic endometritis from an otherwise normal endometrium in the premenstrual stage in which round cells together with glandular hyperplasia, hypertrophy and irregularity, misled Ruge to coin the name "glandular endometritis."

The author then presents his observations from the study of these records and attempts to assess how far this survey fits in with the current conception of chronic endometritis. The various pathological pictures described in these records are classified into eight groups, presented in a tabulated form in order to see how far they satisfy the criteria laid down for the acceptance of the condition described as chronic endometritis. The author discusses in detail the findings in these various categories of classification.

By observing closely for the three characteristic features as required by the modern conception of the subject, particularly the presence of large numbers of plasma cells, only 1 case of true chronic endometritis among the 223 cases was found. The rest of the cases would appear to be doubtful.

The author discusses the significance of the presence and absence of plasma cells in the various pathological conditions of the endometrium. In certain of these conditions, as, for example, in tuberculous of the endometrium, the plasma cells are not detected and the presence of lymphoid cells is depended upon mainly for the diagnosis. In conclusion, the author states that less confusion will result if the 3 characteristic points relative to the modern conception of endometritis are remembered.

HARRIET F. THURGOOD, M.D.

Barrett, C. W.: The Place of Surgery in Fibroids of the Uterus. *Am. J. Surg.* 1944, 66, 148.

The author discusses the history and the current treatment of fibroid tumors of the uterus. He outlines the indications and contraindications for various methods of dealing with the tumors and concludes that they should be treated by one of the following methods:

1. Observation for small asymptomatic tumors.
2. Surgery for larger symptom-producing tumors, particularly in young women in whom the genital functions can be preserved for large tumors at the menopause or for tumors in the postmenopausal patient in which evidence of activity is found.
3. Radiation castration for small tumors at the menopause when the only symptom is bleeding and when there is no contraindication to radiation.

J. ROSSAR WILLSON, M.D.

TeLinde R. W., and Galvin, G.: The Minimal Histological Changes in Biopsies to Justify a Diagnosis of Cervical Cancer. *Am. J. Obs.* 1944, 45, 774.

From a study of the material from 11 cases, the authors have concluded that the abnormal cellular activity which eventually results in fully developed cancer begins in the basal cells of the surface epithelium. In the normal cervical epithelium there is a single layer of fat spindle cells forming the basal layer. They stain deeply with hematoxylin. The transition from this normal picture to extreme basal-cell hyperactivity involving the full thickness of the surface epithelium may be shown histologically in a variety of ways. The normal and hyperactive epithelium may be demarcated by the often-described short oblique line of Schiller. The authors have observed more often however a gradual transition from slight overactivity to a complete involvement of the full thickness of the epithelium by hyperactive epithelial cells. On the other hand, they have rarely observed an absolutely abrupt change. Regardless of the manner of transition, when the full thickness of the epithelium is made up of this hyperactive basal epithelium, the ultimate picture is the same. There is a complete loss of the normal stratification of the cells, the cells and especially the nuclei are irregular in size and shape and a variable number of mitotic figures are present.

After the hyperactive basal epithelium, the next step is invasion of the subepithelial tissue. The glands seem to afford a favorite route for invasion of the underlying tissue. The columnar epithelium lining the gland is destroyed as the epithelium advances. When the base of the gland is reached, the malignant epithelium continues its growth into the depth of the tissue. There is a distinct difference between this process and that seen when the columnar lining of a gland is replaced by the benign

process of epidermization. Aside from the difference in character of the individual cells taking part in invading the gland there is the difference that when the lumen of the gland is filled in its length and breadth by the epidermization process the growth ceases, whereas the malignant growth continues into the adjacent tissue.

There is the strong suggestion that all epidermoid cervical cancer arises in the basal-cell layer regardless of what cell type predominates ultimately in the fully developed cancer.

The astonishing thing in making this study was the frequency with which these lesions occurred in the authors' laboratory. Eight of the 11 cases were found within a twelve month period. During the time, 704 cervical biopsies were made. This incidence was much greater than any that had ever occurred in the laboratory during any corresponding period of time. Certainly it behooves the gynecologist who performs subtotal hysterectomy frequently to perform biopsy freely of all cervixes on the slightest suspicion. EDWARD L. CORNELL, M.D.

Melno, C. B., Broders, A. C. and Munsey, R. D.: Pathology of Malignant Neoplasm of the Cervix Coincident With Pregnancy. *A. J. Obs.* 1944 48 806

A study of 3,570 cases of carcinoma of the cervix observed at the Mayo Clinic in approximately thirty-two years revealed that pregnancy was present in 26 or 0.7 per cent, of these cases when the carcinoma was found. This figure does not necessarily indicate the true incidence of carcinoma of the cervix coincident with pregnancy as all of the 3,570 patients came to the clinic because of carcinoma of the cervix and not because of pregnancy. In the same period covered by this study 8,500 pregnant women were observed at the clinic.

The average age of the patients in the 26 cases in which carcinoma of the cervix was coincident with pregnancy was thirty-two years. The youngest patient was twenty-five years of age and the oldest was forty-one years of age. The prognosis was no worse in the young patients than it was in the older ones.

The average number of previous pregnancies was 6 and the average number of children was 4. The number of pregnancies apparently did not affect the prognosis. In cases in which the carcinoma was diagnosed in the later months of pregnancy the lesion usually was well advanced and the prognosis was poor.

Pregnancy may occur after carcinoma of the cervix has developed. A family history of carcinoma was elicited in 7 or 35 per cent, of the 20 cases which were observed five or more years prior to 1941. The prognosis in these 7 cases was better than the prognosis in the remainder.

Bleeding was the initial symptom in 23 or 88.5 per cent, of the cases. In 25 per cent, the patients did not realize that they were pregnant when the diagnosis was made.

No definite conclusions can be drawn concerning the relative value of irradiation therapy; however, it appears that operation is preferable in cases in which the lesion is operable and that supplementary irradiation increases the percentage of good results. This is in contrast to the relative value of irradiation therapy and hysterectomy in cases of carcinoma of the cervix in which the patients are not pregnant.

The authors are in general agreement with Strauss concerning the treatment of carcinoma of the cervix coincident with pregnancy. If the extent of the lesion permits operation and if the fetus is not yet viable, total hysterectomy is followed by irradiation. If the lesion is operable and the fetus is viable, cesarean section is followed by panhysterectomy and postoperative irradiation.

In cases in which the lesion is nonoperable and the fetus is viable, cesarean section is followed by irradiation. In cases in which the lesion is nonoperable and the fetus is not yet viable, sufficient irradiation is employed to treat the lesion; abortion occurs.

In cases in which the lesion is operable, total abdominal hysterectomy has produced the best results. In 57 per cent of the cases in which this procedure was employed, the patients were free of recurrence five years after the operation.

In this series of cases of carcinoma of the cervix coincident with pregnancy, many of which were observed before the present methods of treatment were developed, the prognosis appeared to be at least as favorable as the prognosis of carcinoma of the cervix that is not associated with pregnancy. Of the 20 patients who were followed up, 30 per cent were free of recurrence five or more years after they had been treated at the clinic.

Schlink, H. H., and Chapman, C. L.: Cancer of the Cervix Uteri, 1930-1942. *Med. J. Australia* 1944 1 377

In 1929 the three clinical schools of Sydney agreed to adopt different forms of treatment for cancer of the cervix uteri and then meet every five years to compare results. The Royal Prince Alfred Hospital was allotted the task of recording the results from the use of radium combined with surgery. Chapman and Schlink have kept faithfully to the plan arranged but for some reason or other there have never been the five-year scheduled comparisons with the other groups.

Ten years have elapsed since these two authors started to record their results in detail and they believe their presentation to be of interest to cancer workers not only in Australia but wherever interest is taken in the subject.

In the past they believe overenthusiastic advocates of particular methods of treatment have prevented the real truth from being discovered. Furthermore, they are strongly of the opinion that relative statistics have led to confusion and that nothing but absolute statistics should be accepted as the standard for comparing figures presented by the various clinics of the world.

TABLE I—RESULTS OF TREATMENT

Condition of Patients	Five Year Statistics, Royal Prince Alfred Hospital 1920-1925		Aggregate Figures from Sixteen World Centers (Bourne and Williams)	
	Cases	Per cent	Cases	Per cent
Patients seen with view to treatment	28		2,051	
Patients treated: 10 cancers microscopically proved	46	5.1	7,052	87.8
16 local recurrence after five years	7	30	2,194	27.6
Dead of cancer	34	6.6	5,768	67.5
16 with recurrence at or in five years	3		18	4
Dead of operation (subjected to operation)		1.5		
Dead of radium treatment (54 cases)				
Dead of recurrent disease		6		
Lost				3
Five-year cure percentage among all patients seen		18.6		
5 cur survival rate among all patients seen		29.4		1.6

Attention is directed to Bourne and Williams who have published in their fifth edition of "Recent Advances in Obstetrics and Gynecology" a clear analysis of often conflicting results in the treatment of cancer of the cervix uteri by radiotherapy. The summarized figures from sixteen world centers are here available so as to be understandable even to the busiest general practitioner.

The method of treatment used by these authors has been to give all the patients treated one full dose of radium, from 5,000 to 7,000 mgm.-hr. with 1 mm. of platinum screenage to the uterus and 2 mm. of platinum screenage to the vagina, and after five weeks those considered operable were submitted to Wertheim's radical hysterectomy.

The above table shows that the use of surgery in addition to radium saves an extra 4.4 per cent of all patients examined over those treated by radiotherapy alone.

The 246 patients treated, 84 of whom have qualified for the ten year statistics, show that the cure rate of radium treatment and surgery fell from 56.1 to 55.1 per cent in contrast to the cure rate of radium treatments which fell from 8.1 to 4 per cent. This would indicate that among the five-year cures 50 per cent of the patients treated by radium alone will perish before they reach their tenth year from the commencement of treatment.

In order to discover the best form of treatment for this lethal disease, it would be far better for all workers to discard all those patients who are suitable for palliative treatment only and concentrate on those who may be salvaged. Certainly with the

forms of treatment at our disposal no real advancement in cure can be made unless the patients are seen in the first and second stages. When the fourth stage is excluded in the authors' statistics the results are most enlightening. There were 16 patients in stage 1 treated by combined radium and surgery. At the end of five years 13 or 80 per cent, were alive there were 53 patients in stage 2 and 60 per cent were alive at the end of five years and there were 43 in stage 3 of which 18 or 41 per cent, were alive at the end of five years. This made a total of 112 patients of whom 63 or 56.1 per cent, were alive at the end of five years.

In the 212 cases treated by radium followed by Wertheim's hysterectomy the operative mortality was 3.5 per cent. The operation itself has the advantage of removing invaded lymphatic glands. In the authors' material, 30 per cent of the cases presented carcinomatous glands. Since the majority of radiotherapists admit that treatment by radium or x ray has no effect on cancer in the lymph glands, it is reasonable to suppose that the authors' better results obtained by combined radium therapy and surgery were due to some degree to the fact that 30 per cent of the invaded material was removed by operation.

SAMUEL J. FOX, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Karnaky, K. J.: A New Treatment for Microcystic Ovaries by the Use of Diethylstilbestrol. A Five Year Study. *West J Surg* 94:4, 5:597

The author notes that the question of what to do with the small cystic ovary or ovaries, occurring with or without pain and of less than 5 cm. in diameter has been a problem of the medical profession since the day of Ephraim McDowell. There are still many useful ovaries in young and old women being sent to pathological laboratories because the surgeon on pelvic examination or at operation has regarded them as "microcystic ovaries."

The endocrine control of the ovary is discussed in some detail. The most common cysts of the ovaries and the ones so easily treated by diethylstilbestrol are (1) follicular cysts that originate in graafian follicles by cystic change. These are in reality retention cysts rather than new growths or proliferative processes. These cysts may be due to a thickening of the epithelial covering of the ovary as a result of inflammation, which prevents rupture of the follicles. (2) There is also microcystic or polycystic degeneration of the ovaries which appears as congeries of numerous, tense, thick or thin walled follicles of pea to cherry size, projects above the surface, and gives the enlarged ovary a bossed appearance.

The ovaries are often riddled by retention follicular cysts, which often causes enlargement, pressure, and a fluctuation in the estrogenic blood level. There may be pelvic pain and menorrhagia. With the exception of incomplete abortion, retention cysts of the ovary are the most common cause of abnormal uterine bleeding. In normal menstruation the

Fig. 2. Effect of diethylstilbestrol on small follicular cyst of the ovaries. Diethylstilbestrol causes complete but

temporary atrophy of the ovaries. Diethylstilbestrol can be used for the treatment of microcystic ovaries.

follicular cyst ruptures which throws the ovum into the pelvic cavity or into the fimbriated end of the tube. If the ovum does not rupture then abnormal menstruation occurs.

The action of diethylstilbestrol in favorably affecting abnormal uterine bleeding is based on the fact that it causes temporary atrophy of follicular cysts of the ovary. Under stilbestrol therapy small unilateral or bilateral cysts up to the size of a small lemon will generally regress to a size that cannot be felt by pelvic examination.

A classification of ovarian cysts is presented by the author. The details of the administration of stilbestrol to a group of patients with cystic ovaries are given.

Diethylstilbestrol which causes a temporary atrophy and complete obliteration of the follicular cysts of the ovaries, can be used to evaluate the condition of the ovary, hence the author notes that we can tell without opening the abdomen whether or not the ovary should be removed in approximately 98 per cent of the cases.

If the patient is given 5.0 mgm of diethylstilbestrol every night for thirty or more nights and the ovarian cyst or cysts still persist then one can feel that he has a very good indication for subjecting his patient to a laparotomy. Normal ovaries will undergo atrophy while abnormal ovaries will not hence diethylstilbestrol used preoperatively will save many needless operations because if the ovary is atrophic

and free of follicular cysts, then that ovary may be left in and the operator may feel that he has not left in an abnormal ovary. On the other hand, if the ovary or ovaries have not become atrophic and devoid of follicular cysts the operator will have a good criterion as to which ovary or ovaries to remove. This would save many normal ovaries that are now going to the pathological laboratories.

If one feels an enlarged ovary from 3 to 5 cm in diameter and if it does not get smaller after giving 5.0 mgm. of diethylstilbestrol every night for twenty or more nights, then an operation is in order. If the ovary is about 3 cm. in diameter then 3.0 mgm of diethylstilbestrol can be given every night for forty nights.

HENRY F. THURSTON, M.D.

EXTERNAL GENITALIA

Ayre, J. E.: Cyclic Ovarian Changes in Artificial Vaginal Mucosa. *Am. J. Obst.* 1944 48 690.

A case of congenital absence of the uterus, vagina and hymen is presented with a simple method of producing a satisfactory artificial vagina without resort to major surgery. The patient was kept ambulatory.

The patient was hospitalized and under anesthesia an opening was made between the bladder and the rectum to admit one finger. No further penetration was attempted at this time because of the extremely thin membrane between the rectum and bladder. The new passage was devoid of any epithelial lining.

and in an effort to keep it open a wax mold (dental wax) was inserted this was lubricated with sulfa thiazole paste.

The patient was allowed to leave the hospital in a few days the obturator being held in place comfortably by a common menstrual belt and pad. She was seen each week when the mold was removed, the cavity cleaned out and the marginal rim of the vulval mucous membrane was cauterized with 30 per cent silver nitrate. On each visit it was observed that the squamous epithelial zone had crept a little higher up the canal to form a sleeve around the obturator until finally the entire canal was covered.

Cyclic ovarian changes have been demonstrated in the artificial vaginal mucosa with differentiation of the two phases (follicular and luteal) in the vaginal smears. A cornification curve representing the variable quantitative level of estrin secretion would appear to follow the approximate anticipated pattern in accord with the cyclic phases. The approximate times of ovulation and menstruation have been hypothesized. **LEONARD L. CORNELL, M.D.**

MISCELLANEOUS

Widenius, I. E.: A Study of Commercially Manufactured Catamenial Tampons. *Am J Obst Gyn*, 48: 30.

A study of 6 commercially manufactured tampons used for the control of the menstrual flow in women was conducted on a group of 25 women of varying ages and pelvic types. Five of the 25 women subsequently desired childbearing and succeeded therefore the use of tampons does not prevent conception. Nine of the 25 women had used tampons at some time previous to this study which indicated a fairly widespread acquaintance with the use of tampons as a method of controlling the catamenial flow.

Description of the amount of flow by a patient is not always consistent with the number of pads used, which indicates that adequate protection can be judged only by correlating the length of complete protection with the definite amount of menstrual flow which can be determined only by weight.

Seven of the 25 women had cervical erosions, but only 2 of the 7 had used tampons previously. Of the 2 who had used tampons previously one had a lacerated cervix resulting from childbirth and the other had an erosion which is commonly classified as a congenital erosion of the cervix.

Four of the 6 tampons were inserted manually by the women and 2 were inserted by the use of individual inserters. The use of an inserter permits proper placement of the tampon within the vaginal tract without contamination by the fingers. Three of the 6 tampons were of the nonexpanding type with a fixed length. Tampon No. 1 was the shortest, being only 1 3/4 inches. Tampons No. 3 and No. 4 were both over 2 inches in length. Clinical findings favor the shorter tampon.

The remaining 3 tampons were of the expanding type. Tampon No. 2 had a fixed length of 2 3/4 inches and expanded only laterally. The 2 others expanded both laterally and lengthwise. Tampon No. 7 had a fixed length of 4 inches before compression and the other tampon, No. 12 had a fixed length of 2 inches before compression.

Roentgenogram visualization of the position in action of catamenial tampons indicates that tampons approximately 2 inches in length are least likely to detect the cervix in the average woman. Tampons with a rounded base are readily removed.

The study taken as a whole leads to the conclusion that catamenial tampons can be used by the average woman to control an average catamenial flow with safety, comfort and complete protection, provided that a short tampon is properly placed well into the introitus. **EDWARD L. CORNELL, M.D.**

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Hill, J. H. and Trimble, W. K.: Placental Infarction as a Diagnostic Criterion of Maternal Toxemia. *Am. J. Obst.* 1944 48 632.

The placentas from 640 consecutive deliveries were fixed in 10 per cent formaldehyde solution for from four to six weeks and then examined grossly for certain infarcts involving necrosis of the villi. Forty-two placentas were from patients with a definite clinical picture of toxemia.

Upon examination only 8 of these 42 placentas from cases of toxemia had such infarcts which were extensive enough so that they could be distinguished from placentas of nontoxemia cases. Thirteen of the 593 placentas from patients with normal pregnancies showed infarcts like the 8 from the cases of toxemia.

The authors were unable to satisfy themselves that they could definitely state that the acute type of infarct described by Bartholomew and his co-workers was associated with toxemia.

In 25 placentas, the cord was drained. There were no instances of congestion when this was done. The administration of pituitrin at the end of the second stage of labor did not affect the incidence of congestion. Congestion might obscure some placental infarcts.

EDWARD L. CORNELL, M.D.

LABOR AND ITS COMPLICATIONS

Persall, J. T., and Torpin, R.: Placenta Previa: Report of 170 Cases. *J. M. Ass. Georgia*, 1944, 33: 297

This is a study of a series of 170 cases of placenta previa observed in the University Hospital in Augusta, Georgia and extends over rather a long period about twenty years. All cases were treated by many physicians and various members of the staff.

The most valuable contribution of the paper is that it shows the relative racial frequency of placenta previa among negroes and whites. The racial proportion of the population in the vicinity of Augusta, Georgia is 58 per cent white and 42 per cent negro and the authors think that this study shows that placenta previa is more common in the white race than in the colored race—in about the ratio of 64 to 36. It would also seem to indicate that the condition is relatively rare in primiparous negroes. Among the 170 cases of placenta previa 15 deaths occurred a total mortality of 8.5 per cent. Hemorrhage was the principal factor in 10 of these deaths, and infection in 5. It should be stated that 4 cases reached the hospital moribund and death could not be avoided by the obstetricians.

Only 21 per cent of all cases received a transfusion which is a very low figure compared with the present trend, but when one considers that these statistics were compiled over a period of twenty

years it is probably a fairly good percentage when put on a comparative basis with other institutions over the same period of time. As the authors state the lesson to be learned from this high mortality record is that every woman should be within range of a blood bank with at least 4 pints of blood of each type available at all times, and that women should be taught the danger of third trimester hemorrhage.

The authors' method of choice for treating this condition is apparently cesarean section, but in certain cases in which the patient is multiparous and the condition is favorable, a Voorhees bag should be used and followed by version if bleeding again occurs as the bag comes out. CHARLES E. GALLOWAY, M.D.

NEWBORN

Sandifer, S. C.: Premature Birth (Analysis of 1 000 Cases) Incidence Etiology and Immediate Result to the Baby. *J. Obst. Gyn. Brit. Empire* 1944 51 408.

The Statistical Review of the Registrar General for England and Wales disclosed that in 1938 there were 24,729 stillbirths 17 572 neonatal deaths and 621 204 live births. Roughly half of the stillbirths and neonatal deaths were associated with prematurity which gave a combined death rate associated with prematurity of 33.1 per 1,000 total births.

An analysis of 1,000 cases of premature birth was made to determine the causative factors. The incidence of premature labor at Queen Charlotte's Maternity Hospital was 8.11 per cent. In the registered group it was 6.78 per cent and in the emergency group 17.2 per cent. One hundred and ninety premature labors were induced in the registered group of 781 which yielded a corrected premature birth rate of 5.13 per cent.

No cause for premature birth was found in 372 (37.2 per cent) of the cases. Induction accounted for it in 319 (31.9 per cent) and abnormalities of the mother and fetus were the causes in the remaining 309 (30.9 per cent). The indications for induction and the abnormalities associated with spontaneous premature labor are shown in two charts.

The stillbirth rate in this group was 25.2 per cent the neonatal death rate was 14.4 per cent and the total death rate 39.6 per cent. With regard to fetal size these statistics revealed the usually expected mortality rates.

The author believes that obstetric pathology was associated with the majority of the premature labors. Medical complications were no more frequent in the premature children than in the mature. Prenatal care adequate diet, and sufficient rest in the latter part of pregnancy should reduce the incidence of the most common causative factors such as toxemia, multiple birth and antepartum hemorrhage.

JAMES F. DONNELLY, M.D.

Lubinski, H., Benjamin, B. and Stream, G. J.: Observations on the Rh Factor in Its Relation to Hemolytic Anemia of the Newborn Infant. *Am. J. Obst.* 1944, 48: 464.

In six families there occurred 6 cases of hemolytic anemia of the newborn, and there was evidence that 7 other infants had probably suffered from this disease.

Common to all of the cases tested was the combination of the following conditions: the mother was Rh-negative, the father was Rh-positive (only one father was not available for testing) and the infant was Rh-positive. All the mothers had anti-Rh agglutinins in their sera.

Immunization of an Rh-negative woman by repeated transfusions of presumably Rh-positive blood was later followed by fatal hemolytic anemia of her first newborn infant. Rh-negative females should not be transfused with Rh-positive blood to prevent the possibility of this undesirable effect upon any future Rh-positive offspring.

A possible role of complement and of the liberation of hemolysins after the destruction of red blood cells in the clinical picture of hemolytic anemia of the newborn is discussed.

No correlation was found between the titer of anti-Rh agglutinins in the mother's serum at parturition and the severity of hemolytic anemia in her newborn infant.

As the treatment of choice for this disease, the infant should be given a transfusion of a concentrated suspension of washed Rh-negative red blood cells as early as possible and this should be repeated as often as may be necessary. A suspension of washed cells from the mother's blood may be used if no suitable donor is available. Washed cells from the mother's blood should be used in any case in which the mother and her newborn infant who shows evidence of the disease are both Rh-positive or both Rh-negative. EDWARD L. CONNELL, M.D.

Starrock, J.: Obstetrical Responsibility in the Prevention of Fetal and Neonatal Deaths. *Edinburgh M. J.* 1944, 5: 147.

The stillbirth and infant mortality rates in Scotland are high. In Scotland in 1939 there were 108 deaths per 1,000 total births, 43 were stillbirths, 35 were neonatal deaths (deaths before one month of age) and 31 were deaths occurring between the end of the first month and the end of the first year. This compares unfavorably with New Zealand, Holland, Canada, England, and Wales. In Scotland over 70 per cent of these fatalities are due to stillbirths and neonatal deaths. In view of the records for the next eleven months the authors believe that control of postnatal infection—especially pneumonia and gastroenteritis—is the secret of successful reduction of these deaths.

The problem of how to diminish the number of stillbirths and neonatal deaths is primarily an obstetrical responsibility as an examination of their causes makes obvious.

We have no knowledge of how to prevent congenital defects but there is a considerable accumulation of information regarding the control of prematurity, asphyxia, and intracranial hemorrhage. An appreciation of these causes of death and the factors that produce them and the faithful application in daily practice of methods that control them are the contributions which obstetricians, family doctors, and midwives can make.

Prematurity, now defined as a viable child weighing 5½ lb. or less at birth is of great importance. Prematurity was a factor in 436 about 50 per cent, of 813 stillbirths and neonatal deaths although it was considered to be the primary cause of death in only 43 cases. Immature children are more vulnerable to the other lethal factors of asphyxia, cerebral hemorrhage, and infection than full-term children.

In 66 per cent of the fully investigated cases of death among premature infants in the Maternity Pavilion there was an associated abnormal pregnancy. The main complications were antepartum hemorrhage in half (48 per cent) of these abnormal pregnancies and preclampsic toxemia and eclampsia in a fifth of them while hydramnios, pyelitis, and cardiac disease were less frequent factors. In the remaining third of these premature cases the pregnancy had been normal until the onset of labor but no satisfactory explanation of the early onset of labor could be found.

Can anything be done to prolong these gestations? Recent experiments and observations have shown that the correction of dietetic deficiencies appears to play a part in reducing the incidence of premature labors and helps to control the development of the more serious manifestations of toxemia, so that the necessity for termination of pregnancy can be delayed. Accidental hemorrhage is often linked up with pre-eclampsic toxemia and hypertension and, in the absence of these, the possibility of a vitamin C deficiency has been suggested as an etiological factor. Education in the matter of diet is one practical step we can take in our antenatal clinics and private practice. In addition to diet, the provision of proper rest and house help for pregnant women would also be beneficial.

Asphyxia was the actual cause of death in 40 per cent of the stillbirths and 30 per cent of the neonatal deaths. It is produced in at least four common ways: premature separation of the placenta, obliteration of the cord circulation, prolonged labor and the development of anoxemia from overdosage of the mother with analgesic drugs or during general anesthesia when cyanosis is allowed to occur. Premature inspiration is probably more commonly the result of developing asphyxia and of course aggravates it.

Premature separation of the placenta, frequently complicated by immaturity of the fetus, accounts for a high proportion of fetal deaths due to asphyxia. In the cases seen from 1940 to 1943 in the Simpson Maternity Pavilion it occurred in 129, or 45 per cent, of the 285 fatalities confirmed by postmortem examination as primarily due to asphyxia. Our present

state of knowledge does not permit of our taking steps to prevent placenta previa or accidental hemorrhage with the possible exception of counteracting the factor of malnutrition which accounts for some cases of accidental hemorrhage. Therefore these fetal deaths must largely be considered non preventable. It should be remembered however, that avoidance of overtreatment in minor degrees of placenta previa and recourse to cesarean section in the major degrees especially if the child is near term not only preserves some fetal lives but is usually safer for the mother.

Fetal asphyxia due to the other causes, obliteration of the cord circulation prolonged labor and anoxemia during anesthesia, is for the most part theoretically preventable although again prematurity creeps in as a factor. Obliteration of the funic circulation is encountered most in prolapse of the cord, either obvious or occult but at least partial occlusion is not infrequent when loops of cord around the neck result in a relative shortening of it so that it is drawn tight during the perineal stage a condition fraught with some danger to the child if there is delay in delivery more likely in a primigravida. A cord complication is always to be suspected if there is no antepartum hemorrhage or prolonged labor to account for signs of fetal distress. Auscultation of the fetal heart should be practiced throughout labor. Special attention to its rate and character is necessary during the half hour that follows rupture of the membranes and during the perineal stage of labor. If the head is high when the membranes rupture, a rectal or preferably a vaginal examination should be made to see if a loop of cord has prolapsed. Early recognition gives the best chance of selecting a successful line of treatment for this complication which is so dangerous for the fetus. A cord drawn tightly around the child's neck is to be suspected if there is a serious reduction in the fetal heart rate or if meconium appears when the head is showing at the vulva. Between pains recession of the head is often considerable because of the relative shortening of the cord. Application of the forceps or an episiotomy or both, to expedite delivery will usually rescue the child. To facilitate auscultation of the fetal heart during this stage of labor it is helpful to keep the patient on her back till delivery is imminent.

A long labor is well known to have an adverse effect on the child. In some cases of prolonged labor the cause of death is cerebral hemorrhage, in others an intrantracheal pneumonia has developed but in the majority asphyxia is the postmortem finding. The mechanism of its production may be that the uterine musculature in time fails to relax completely between contractions, and the resulting increased tonicity produces a prolonged low-grade anoxemia by interfering with the placental circulation and eventually results in intrauterine death of the child. Cruikshank emphasized that direct damage to the respiratory center by edema, produced by prolonged and excessive, increased intracranial pressure rather than gross hemorrhage was the most common post

mortem finding in babies dying of respiratory failure. Holland has suggested crowding down of the medulla oblongata into the foramen magnum as the cause. These dangers are increased if the membranes are ruptured.

Prophylaxis in this group begins with adequate antenatal care so that likely mechanical difficulties in labor such as disproportion and malpresentation are recognized. It becomes necessary to make a very careful assessment in a case of prolonged labor when its duration has exceeded thirty hours. If progress is being made even slowly as judged by improved efficiency of the uterine contractions, increasing dilation of the cervix, and descent of the presenting part and the general condition of the mother and child remain good and a safe vaginal delivery can be visualized further conservatism is justified otherwise an operative delivery should be undertaken. When the head is low in the pelvis and the cervix is more than half dilated manual dilatation or cervical incisions and delivery with the forceps are reasonable. When the head is high the cervix less than half dilated and there is no sign of maternal infection a lower segment cesarean section is called for in the interest of both patients.

Anoxemia due to overdosage with analgesics or the development of cyanosis during general anesthesia are occasional but preventable causes of fetal death.

In the treatment of actually developed intrauterine fetal distress the administration of oxygen to the mother along with a general anesthetic that will inhibit uterine contraction is valuable. When a child showing respiratory failure is born prompt treatment is necessary. The blue and white forms of asphyxia neonatorum are only degrees of the same condition and both may be due to a central or peripheral cause. In both the initial treatment is warmth clearing the air passages with a swab or mucous extractor and gentleness in handling. All methods of artificial respiration are to be avoided as these simply increase shock and may cause actual organic injuries. If there is no satisfactory response and when possible 95 per cent oxygen with 5 per cent carbon dioxide should be administered and 1 cc. of coramine or lobeline hydrochloride (0.003 gm in 1 cc. of sterile water) injected. The passage of a pharyngoscope and tracheal insufflation may be given consideration.

In the maternity-pavilion series of postmortem examinations, cerebral hemorrhage was found in 44 breech 45 forceps, and 50 spontaneous vertex deliveries, as well as in 3 children delivered by cesarean section. As spontaneous vertex deliveries are by far in preponderance and deliveries with the forceps are more than twice the number of breech deliveries, the incidence of this lesion is highest in breech and lowest in spontaneous births.

In the spontaneous group too quick a labor often has subjected the head to too rapidly changing strain and stress. In contrast to too quick labor the excessive head molding associated with a labor prolonged

because of a degree of disproportion can produce laceration at the attachment of the falx cerebri to the tentorium cerebelli even when the delivery is spontaneous.

The obstetrical forceps can damage the cranial contents in three ways. It can be applied to the wrong diameters of the head or be used with excessive force or the head can be extracted too rapidly. The influence of all these is naturally much greater in the less well protected head of a premature fetus. The forceps should, therefore, be avoided except for a sound obstetrical indication. Before applying the forceps to a healthy fetus, one should be as certain as possible that the head can be delivered by this means. Realization of this important decision largely accounts for the replacement of the high operation by the lower-segment cesarean section. When the forceps is applied least damage to the child will result if the blades are placed at the sides of the fetal head so that the ears lie within the fenestrated blades with the occiput anterior. To obtain this good cephalic grip is not always easy if the head has not rotated anteriorly so that the sagittal suture lies in the anteroposterior diameter of the pelvis—a state of affairs found only when the head is on the perineum. Undue haste in the actual extraction has the same effect on the cranial contents as a precipitate labor and this temptation must be resisted.

In breech deliveries the incidence of fetal intracranial hemorrhage is high. It is caused by the un-

molded and often imperfectly flexed head being brought too quickly through the bony pelvis. In a primigravida there is the important additional resistance of the incompletely dilated vagina and vulvar muscular ring.

An important recent additional aid in reducing the risk from or the extent of, intracranial hemorrhage in the newborn is the administration of vitamin K to raise the prothrombin content of the fetal blood. When the occurrence of cerebral damage is likely vitamin K can be given to the mother by mouth or by injection from twelve to four hours before delivery or by injection to the infant after birth.

Fetal deaths and a proportion of neonatal deaths are caused either by hazards that exist before birth or by hazards that arise during birth itself. Their reduction is possible, as other countries have shown, and the ways and means are primarily an obstetrical responsibility. Adequate maternal nutrition so closely linked to improvement in social and economic standards should help reduce fetal deaths by diminishing the incidence of prematurity and possibly limiting toxemia as well as eventually eliminating contracted pelvis. Better practical midwifery in which judgment and technical skill are equally important and necessary in order to deal with difficult and prolonged labor should bring about some reduction in the number of theoretically preventable neonatal deaths.

CHARLES BARON, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Calp, O. S.: *Renal Ectopia; Report of 6 Cases.*
J. Urol., Balt., 1944, 58: 470.

Six cases of renal ectopia were found among 747 patients who were studied pyelographically during a single year a clinical incidence of 1:125. Most reports indicate that ectopia in its many forms should not be anticipated this frequently.

Three patients had simple unilateral ectopia. Although in 70 per cent of the published cases the ectopia was on the left side, in 2 of the author's group it occurred on the right. The most common location for simple renal ectopia is in the true bony pelvis, but in none of these cases was this location correct. Only 1 of the 3 ectopic kidneys presented secondary disease, but all 3 patients had symptoms referable to the kidney.

Two patients had crossed ectopia with fusion. This anomaly usually is found on the right side. Both of the fused kidneys were on the left. The lower kidney was ectopic in both instances. Secondary disease was present in only 1 case but this explained the symptoms referable only to the upper urinary tract.

One patient had crossed ectopia without fusion. The kidney was hypoplastic also. The normally placed right kidney had duplication of the pelvis and ureter and compensatory hypertrophy. The patient's only symptoms were nocturnal enuresis.

Two of these 6 patients had also congenital anomalies of the skeletal system. No genital abnormalities were present, although they were common in previous reports.

The facts that 2 patients had no symptoms referable to the upper urinary tract and no secondary disease, and that 2 others had symptoms only while the superimposed disease existed, add support to the contention that symptomatology usually is due entirely to secondary changes in ectopic kidneys. However 2 patients with pain reproduced by filling the ectopic pelvis and with no secondary disease, indicated that the ectopia per se may in selected instances be capable of causing discomfort.

JOHN A. LOFF, M.D.

Jacobs, A.: *Transplantation of the Ureters into the Bowel.* *Glasgow M. J., 1944, 143: 97.*

In certain congenital and acquired conditions of the urinary bladder the organ is totally incapable of carrying out its function of retaining urine or it has a capacity which is only a mere fraction of the normal. In the one instance there is complete incontinence and in the other severe day-and-night frequency. When the condition is not amenable to cure, deviation of the urine from the bladder is necessary. In the treatment of primary vesical carcinoma by total cystectomy deviation of the urine is necessarily the

first stage. Nephrostomy and cutaneous ureterostomy are less attractive measures than ureterosigmoidostomy and the author utilizes these measures only as palliative treatment when the life expectancy is not great.

After it has been established that deviation of the urine from the bladder is indicated intravenous pyelograms are made to show the function of the kidneys and the morphology of the ureters. The patient receives a low residue diet for one week and for three days before operation a mild aperient such as petrolagar is given thrice daily. In addition a soap and water enema is given in the morning and a colonic irrigation in the evening. A final lavage is given the morning of operation and the patient comes to the operating theater with the tube in the rectum. Sulfathiazole, 1.0 gm. every six hours in addition to sulfiaguanidine is given for three days preoperatively and the fluid intake is kept at 5 pints.

The operative procedure is fundamentally the Coffey operation No. 1. Through a midline incision the peritoneal cavity is entered and the intestines are packed into the upper abdomen. The posterior peritoneum is incised the ureter is amputated as low as convenient, and a ureteral catheter is inserted. The serosa and muscularis of the pelvic colon are incised for a distance of 2 inches and the ureter is placed in its new bed without angulation. The first row of sutures is placed in the muscularis of the colon to hold the ureter in place. Then the mucosa is incised and the ureter is carried into the lumen of the bowel and held in place by a single gut suture. The distal ureter is incised 1.5 cm. longitudinally to prevent contracture of the orifice. A second row of sutures is placed in the muscularis of the colon, and the posterior parietal peritoneum is closed. Ordinarily both ureters are implanted at the same operation.

Postoperative care involves the use of a rectal tube for six days and a continuous intravenous drip for the first forty-eight hours. About 4 pints of 5 per cent glucose in saline solution and 2 pints of 4.285 per cent sodium sulfate for each twenty-four hours are administered. Pituitrin (3/4 cc. every six hours) has been useful to combat intestinal distention. A mild laxative is given on the fourth day and continued in varying amounts until at least one daily formed motion results. After removal of the rectal tube a variable period of frequency follows, but usually by the end of four weeks an interval of from three to four hours is quite common with a still longer period at night.

The indications for ureterosigmoidostomy are vesicovaginal fistula resistant to surgical repair, vesical contracture due to encrusted cystitis, Hunner's ulcer and tuberculosis, congenital malformation of the urinary bladder, urethral injury beyond

repair and carcinoma of the urinary bladder to be treated by total cystectomy.

The operative mortality in 38 cases was 31.5 per cent, while in 13 cases of vesicovaginal fistula the mortality was only 7.6 per cent. Patients with chronic urinary infections or with tuberculosis or malignant disease are poorer operative risks and consequently a greater mortality is expected.

Following ureterocolicostomy the life expectancy is not appreciably altered. The first patient in the series is alive and well twelve years later. The fear still entertained that transplantation of the ureters must be followed by a serious ascending renal infection with decreased renal function and consequent poor prospects of life expectancy has been greatly exaggerated.

DONALD F. McDONALD, M.D.

BLADDER, URETHRA, AND PENIS

Crisol, D. S., Greene, L. F. and Thompson, G. J.: Interstitial Cystitis of Men. *J. Am. M. Ass.* 1944 36 85.

On the basis of a review of 78 cases of interstitial cystitis in men the following conclusions were drawn:

1. Although interstitial cystitis is predominantly a disease of women it is found to have a significant incidence among men. A search for evidence of interstitial cystitis among male patients will explain a number of cases of puzzling and intractable cystitis.

2. The clinical picture among male patients is often deceiving because of accompanying obstructive symptoms, especially in the prostatic age group.

3. Still more deceiving are the cases in which obstructive symptoms are superimposed without any obstructive pathological change. In those cases the obstructive symptoms are part of the picture of cystitis and will be found to be relieved by treatment of the cystitis rather than by a prostatic operation.

GENITAL ORGANS

Swyer, G. I. M.: Some Observations on the Pathological Anatomy of Benign Prostate Enlargement. *J. Path. Bact., Lond.*, 1944, 56 365.

Observations on the pathological anatomy of prostatic enlargement with particular reference to the etiology were made upon 238 prostatic patients of all ages, of which 119 were forty-six years old or more and presented the changes of benign enlargement.

The uvula vesicae, a median knob of adenomatous tissue behind the internal urethral meatus, was found to arise from laterally disposed adenomas in 11 of the 15 cases in which this structure was present. It was not present in a patient younger than fifty-seven years. In one patient the uvula originated from trigonal glands and in another case from the preperineal glands.

With serial sections the author has demonstrated that in most cases the tubules of the uterus masculinus do not communicate with the adenomas occurring in benign prostatic enlargement. However in some

cases there was an unmistakable intercommunication between the uterus masculinus and the prostatic ducts.

This evidence might be considered to favor the theory that benign prostatic enlargement is due to hyperplasia of the uterus masculinus. However such participation of muellerian tissue cannot be regarded as indispensable since it is observed so uncommonly. It is the author's belief that the earliest changes of prostatic hypertrophy consist of glandular hyperplasia anterolateral to the urethra in the caudal half of the prostate and involving the most medial of the prostatic glands. In the normal prostate of the third and first half of the fourth decade, hyperplasia of the duct epithelium occurs in just such areas. It would appear that benign hypertrophy begins as an intensification of the growth process which subsequently becomes disorganized in those parts of the prostate which possess the highest growth potential, as evidenced by persistence of normal proliferative activity. The fact that such persistent proliferative activity may also exist in the preperineal lobe would account for the participation of that lobe in some, but by no means in all cases of benign hypertrophy of the prostate.

DONALD F. McDONALD, M.D.

Watkinson, J., Delory, G. E., King, E. J. and Hadow, A.: Plasma Acid Phosphatase in Carcinoma of Prostate; Effect of Stilbestrol. *Brit. M. J.* 1944 2 492.

The authors present details of the method employed for the estimation of acid phosphatase, and of the values obtained for plasma acid and alkaline phosphatase in various clinical conditions and in normal controls, and for acid phosphatase in seminal fluid. Two specimens of seminal fluid from a case of eunuchoidism contained relatively negligible amounts of acid phosphatase.

Of 10 cases of prostatic carcinoma, 6 showed a raised acid phosphatase content in the plasma and in 5 of these there was roentgenographic evidence of metastases in bone. Several of the results do not show any marked distinction between prostatic carcinomas with metastases and Paget's disease.

The behavior of the plasma phosphatases in cases of carcinoma of the prostate in which the plasma acid phosphatase was originally raised was followed during treatment with stilbestrol. The response shows a uniformity of pattern, the acid phosphatase falling abruptly to a normal level, which is then maintained for considerable periods, with a rise in alkaline phosphatase followed by a gradual fall.

Of 10 cases of carcinoma of the prostate, 4 showed some degree of regression of the primary tumor under treatment with stilbestrol, and secondary deposits in lymph nodes underwent regression in 3 cases. X-ray examination at three-monthly intervals in the cases with metastasis to bone revealed in some a progressive increase in density while in others the deposits became more numerous during treatment or increased in size.

With one exception all cases showed some measure of symptomatic and general improvement, in relief from pain, decrease in the frequency of micturition or gradual increase in the hemoglobin level and in improvement in appetite and gain in weight.

JOHN A. LOER, M.D.

Franklin, A. P.: Reconstruction of the Male Genitalia. *Am Rev Seriol Med.*, 1944, 2: 14.

The smallest remnants of the cavernous bodies must be utilized in the reconstruction of the penis in such a way that the erectile functions may be transmitted to the new organ and thus make sexual activity possible. In reconstruction of the urethra, the method used is that developed and reported by Bogura (*Zentralbl Chir* 1936 63: 1 271) but under much more difficult conditions. The operation is performed, as a rule, in four stages: (1) formation of an abdominal skin tube into which rib cartilage is inserted, (2) transfer of the proximal pedicle of the tube and implantation of the cartilage into the remnants of the cavernous bodies, (3) division of the distal end of the tube and formation of the penis and (4) reconstruction of the urethral canal, either as a pedicle from the scrotum immediately beneath the reconstructed penis, its under surface thus becoming the upper wall of the new urethra, or by such a flap taken from the fine skin of the upper arm, or other where.

By this implantation of the cartilage the tumefaction under the influence of the sexual impulses moves the cartilaginous portion of the penis upward and forward so that coitus is possible. During sexual stimulation a light erythema and swelling of the reconstructed penis occurs. At first the absence of the glans penis results in very weak orgasms and ejaculations in time however new erotic zones apparently develop and the orgasm approaches normal intensity.

In summary it may be confidently stated that a procedure which permits reconstruction of a normally functioning genital organ is an important contribution to modern plastic surgery.

JOHN W. BRENNAN, M.D.

MISCELLANEOUS

Beigel, W. T.: Sterile Pyuria. *J Urol.*, Balt. 1944, 52: 283.

"Sterile pyuria" is being recognized as a definite clinical entity. The evidence at hand suggests as the etiologic agent a Gram positive coccus which fails to grow on the usual culture media. The sulfonamides are of little avail in this condition.

The author presents 4 cases with similar histories, findings, and response to treatment. Salient features of the disease are complaint of long standing day and night frequency of urination in an adult accompanied by dysuria and tenesmus. Typically the urine shows 2 to 4 plus albumin, 2 to 4 plus pus and 0 to 1 plus red blood cells with no bacteria apparent on stained smear or upon routine culture. Cystos-

copy and pyelography are uniformly negative. Treatment with sulfonamides is uniformly unsuccessful, whereas 3 or 4 injections of 0.3 gm. of neoarsphenamine are attended by rapid symptomatic and objective improvement. In 1 of the 4 cases Gram positive cocci in chains appeared in the urine following arsenical therapy. The author believes that the appearance of staphylococci after one or more doses of neoarsphenamine in no way makes the diagnosis of sterile pyuria incorrect.

In these 4 cases the results of treatment were rapid and complete. Recurrences have not occurred over follow up periods for as long as five years.

The author concludes that "sterile pyuria" is a definite clinical entity simulating renal and vesical tuberculosis in its symptomatology. The cause of sterile pyuria is probably an organism of the coccus group difficult to grow and hard to find in stained smears. It is probably not a virus since virus diseases do not respond to the arsenicals. It is seldom cured by the urinary antiseptics including sulfa drugs usually employed in renal and bladder infections but responds sometimes in a spectacular manner to arsenicals.

DOMALD F. McDONALD, M.D.

Scarcello, N. S.: Penicillin in Sulfonamide-Resistant Gonorrhea. *N England J M.*, 1944, 231: 609.

The author reports a carefully analyzed series of 200 cases of sulfonamide resistant gonorrhea which were treated with variable initial doses of penicillin ranging from 150,000 to 30,000 units. Fourteen per cent of the cases required two or more courses of penicillin. There were no failures in this group of cases treated and the patients were returned to duty in one-third of the time usually required.

When 100,000 or more units of penicillin were exhibited initially only 9 per cent of the cases required repeat courses while when 80,000 or less units of penicillin were used 17 per cent required repeat courses of penicillin.

In the group treated there were 3 with complicating gonorrheal arthritis and this cleared rapidly with penicillin. Four individuals with prostatic abscess showed immediate improvement with the use of penicillin but the drug seemed to have little or no effect on a complicating epididymitis. No toxic reactions to penicillin were experienced.

The author warns that penicillin may mask the presence of primary syphilis. It is further suggested that although sulfonamides may not affect a case of gonorrhea in an individual, their continued use until penicillin is obtainable will assist in localization of the disease and thus afford a more rapid cure with penicillin.

ROBERT LICH, M.D.

Eagle, H.: The Treatment of Early and Latent Syphilis in from Nine to Twelve Weeks with Triweekly Injections of Mapharsen. *J Am M Ass* 1944 136: 538.

The three major considerations of chemotherapeutic procedures determining dosage and duration

of treatment of syphilis with mapharsen are therapeutic efficacy, toxicity and practicability. Studies on experimental rabbit syphilis revealed that the total curative dose is relatively constant. The toxicity varied directly with the method of administration. These relationships also hold in man. Weekly doses of 60 mgm. are attended by a mortality of 1 in 5,000, whereas when the total dose is given in five days the mortality has been 1 in 500. It was thought that triweekly injections of about 1 mgm. per kilogram would result in a mortality less than 1 in 1,000 and a course of treatment which would last but from nine to twelve weeks.

The clinical study was commenced in 1941 with the co-operation of venereal-disease clinics. With a few exceptions all patients were ambulatory. The dose of mapharsen was between 40 and 80 mgm. (adjusted to body weight) and averaged 60 mgm., this was given three times a week. The duration of treatment varied from four to twelve weeks. About half of the clinics also gave an injection of bismuth each week. Clinics were urged to give quantitative serological tests at least twice during the course of the therapy and monthly thereafter. A spinal puncture three and twelve months following treatment was advised.

Of 4,813 cases treated there were 90 with seronegative primary syphilis, 1,054 with seropositive primary syphilis, 2,050 with secondary syphilis, and 1,190 with latent syphilis. There were 151 patients previously treated for syphilis who were now diagnosed as having an infectious or serological relapse, and 8 with late recurrent syphilis. Forty per cent of the total were white and 53 per cent were male. In evaluating response to treatment, infectious relapse, clinical or serological evidence of central-nervous-system involvement, serological relapse and cases presenting persistently positive blood serology were adjudged as treatment failures. Cases which were strongly suggestive of reinfection rather than relapse were also considered treatment failures.

Evidence of minor toxic reactions consisting of nausea, vomiting, malaise or headache occurred in 16 per cent of the patients and approximately 15 times more frequently in women. In 33 patients or in of every 210 treated repetition of these minor reactions made it necessary to discontinue treatment. In 106 patients a syndrome suggesting sensitization to mapharsen was observed. Reactions in the order of decreasing frequency were fever, rash, vomiting, headache, conjunctivitis, photophobia, and facial edema. Recovery was usual in from forty-eight to seventy-two hours. In a total of 54 patients it was necessary to discontinue treatment. Serious reactions occurred in a total of 39 patients. They consisted of 2 cases of toxic encephalopathy (1:2,400), 7 cases of arsenical dermatitis (1:950) and 21 cases of jaundice (1:15). Seventy-five per cent of these reactions occurred in the second to fourth week of treatment. There were 4 deaths (1:1,500): 2 due to nephritis, 1 to encephalopathy and 1 to jaundice. In 2 or perhaps 3 of these cases death may have been

preventable. Serious toxic reactions tended to occur in young women and negroes. The 4 deaths occurred in negro women 3 of whom were under eighteen years of age.

Therapeutic results in early syphilis when mapharsen alone was given were uniformly poor, with from 9 to 15 per cent failures. When bismuth was also given failures occurred in from 11 to 6.6 per cent. The addition of only 5 injections of bismuth to the smaller amount of mapharsen (less than 21 mgm. per kilogram) increased the fifty to sixty-week "cures" from 49 to 65 per cent.

When 21 mgm. or more of mapharsen per kilogram were supplemented with an average of 9 injections of bismuth, seventy-week "cures" were obtained in 82 per cent. Thus, triweekly injections of from 40 to 80 mgm. of mapharsen combined with weekly injections of 0.2 gm. of bismuth subsalicylate for from nine to twelve weeks will "cure" from 80 to 90 per cent of the cases of early syphilis.

Infectious relapse and serological relapse accounted for 43 and 40 per cent of the failures respectively. Involvement of the central nervous system accounted for 13 per cent of the failures, and 7 per cent of the failures occurred in patients whose positive serology was at a stationary level one year after treatment. The present study gave no indication of a more favorable prognosis in secondary syphilis. In patients with previously treated early syphilis who had relapsed, the number of treatment failures was no greater than in previously untreated cases when both bismuth and mapharsen were given. Good results were obtained with the intensive treatment schedule in latent syphilis. The rate of serological reversal was found to depend upon the initial serological titer but the latter had no effect on the prognosis for early syphilis.

DONALD F. McDONALD, M.D.

Goodall, J. R.: Urinary Complications of Pelvic Endometriosis. *Ann. Surg.* 1944, 70: 891.

Secondary endometriosis seldom involves the urinary organs, but involvement of the urethra, bladder and ureters is reported. The type and degree of involvement of the urinary tract depends upon (1) the histological type of cell involved, and (2) the mode of invasion of the urinary tract.

Stromatous endometriosis arising from non-glandular connective tissue elements of the deep layers of the endometrium does not undergo change with the menstrual cycle. This type of endometriosis secondarily involves the trigone and base of the bladder when there is direct lymphatic continuity with the uterus. The author describes 2 cases of this type in which the whole pelvis was invaded and there was loss of sphincter control with incontinence and cystitis. Mixed glandular and stromal endometriosis arising from the superficial layers of the endometrium undergoes cyclical response with the uterus. This type of endometriosis involves the bladder by implants in the peritoneal vesicouterine pouch and also by traumatic displacement of endometrial tissue to

the peritoneal surface of the bladder following surgery in cases of endometriosis. In 30 per cent of these cases previous pelvic surgery for endometriosis had been performed. As most of these cases are derived from intraperitoneal disease incident to total regurgitation of endometrium they respond to the menstrual cycle and rhythmic hematuria is the most efficient sign of bladder endometriosis. Cystoscopically there is a bladder growth surrounded by edema, congestion and blue grapelike masses. During menses, edema and congestion increase and there is marked hemorrhage. The lesions are predominantly in the dome of the bladder. This picture is in contrast to that found in stromatous endometriosis in which the trigone is involved by pearly white cystic growths varying from the size of a millet seed to that of a bean which do not change in appearance during menses.

The author describes secondary mixed endometrios of the urethra which underwent cyclic changes and responded well to local excision and pelvic irradiation. He also describes secondary involvement of the ureters by ectopic endometrium in 4 cases. Two patients with stromatous endometriosis lived eleven and twelve years after diagnosis with temporary benefit from roentgen irradiation followed by gradual invasion of all the pelvic structures and death due to uremia consequent to ureteral obstruction. Two cases of mixed endometriosis involving the ureters had the presenting symptom of pain in the flank due to hydronephrosis. Treatment of secondary endometriosis involving the urinary tract is similar to the usual treatment of endometriosis. Partial cystectomy for lesions involving the bladder is not recommended.

DONALD F. McDONALD, M.D.

Cannon, A. B., Fisher, J. K., Rodriguez, J. J., Beattie, G. F. and Macchilling, E. *Intensive Arsenotherapy* *J. Am. M. Ass.* 1944 126 544

In the past three years 332 cases of early syphilis in chiefly healthy young men were treated with massive doses of arsphenamine by the syringe method, the treatment period extending over five or six days. Two-thirds of the patients were negroes. All of the patients were hospitalized and given complete physical and laboratory examinations, including quantitative Wassermann tests on serum and spinal fluid, blood and platelet counts, serum bilirubin and urea and cephalin flocculation tests as well as daily determinations of the blood arsenic levels. Frei and Dreyer tests and urethral cultures were made in all

cases. Daily dark field examinations and urinalyses were performed. After discharge from the hospital the patients were seen at weekly intervals in the clinic for the first six weeks and then at monthly intervals.

Treatment consisted of the intravenous administration of a 2 per cent solution of arsphenamine three or four times a day for five or six days according to one of seven plans. The total dose varied from 1.5 gm. to 4.4 gm.

Seven treatment plans were used each new plan having been worked out after analysis of the results of the preceding plan. It was determined that in order to make the dark field examinations negative in twenty four hours it was necessary to give 1.0 gm. in the first day. Healing of surface lesions was prompt and usually complete in one week. Of 332 patients treated only 178 have been followed up from six months to three years. Of these, 118 or 66 per cent were clinically and serologically negative and had normal spinal fluids. Mucocutaneous relapses occurred in 9 cases and failure of the serology to become negative in one year occurred in 12 cases.

There were 12 severe reactions: 1 ending fatally. These included 2 of encephalitis, 3 of hepatitis (1 fatal), 2 of exfoliative dermatitis, 3 of persistent neuritis and 2 of blood dyscrasias. There were numerous minor reactions such as an initial rise of the temperature on the first day which subsided the next day. Secondary rises in temperature and toxic erythemas occurred near the end of the course of treatment, and mild neuritis usually appeared about two weeks after cessation of treatment. As the amount of drug was increased the occurrence of secondary fever increased from 15 per cent to 80 per cent, mild neuritis increased from 2 per cent to 35 per cent and toxic erythemas increased from 8 per cent to 40 per cent. Trace albuminuria was present in 18 per cent. Vomiting occurred in 22 per cent, and diarrhea was present on the first day in 10 per cent.

Laboratory studies of the blood arsenic levels showed that there was always a retention of arsenic long after cessation of treatment. Reactors showed a greater retention of arsenic and for a longer period of time than nonreactors, and the more arsenic received the greater was the retention.

The authors conclude that treatment of early syphilis with arsphenamine by the multiple syringe method over a period of five or six days is ineffective, dangerous, expensive and altogether impractical.

DONALD F. McDONALD, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Wang, K. Liu S. H. Chu, H. L. Yu T. F. and Others: Calcium and Phosphorus Metabolism in Osteomalacia. The Availability of Inorganic Phytin, and Dietary Phosphorus and the Effect of Vitamin D. *Chin. M. J.* 1944, 69

Phytin, the calcium and magnesium salt of inositolphosphoric acid (phytic acid) is a relatively poor source of phosphorus for absorption and utilization by the human organism. Phytic acid is widely distributed in foodstuffs, especially in cereals, in which it constitutes from 50 to 70 per cent of the total phosphorus. It is assumed that phytin is of limited value nutritionally.

McCance and Widdowson who calculated the phytin portion of total phosphorus in the diets of the moderate class population in England, gave an average figure of 5 per cent. In China, ordinary diets are largely composed of cereals. Yang and Dju estimated that in some typical diets in Shanghai, from 24.5 to 50 per cent of the total phosphorus was in the form of phytic acid. In northern parts of China where osteomalacia is prevalent, cereals constitute the main dietary staples. A high cereal diet is not only low in calcium it is high in phytic acid. It is possible that a dietary intake of phosphorus, largely in the form of the relatively unavailable phytic acid, plays a role in the pathogenesis of osteomalacia. The present article deals with the availability of phytin phosphorus in patients with osteomalacia.

Two cases of osteomalacia were studied to ascertain the availability of phytin phosphorus supplied either from cereals or from phytin preparation as compared to its availability when inorganic phosphate (constant calcium and constant total phosphorus) was administered.

When from 30 to 40 per cent of the phosphorus intake was in the form of phytin the absorption and retention of both calcium and phosphorus were decreased, when compared with the absorption and retention following a similar level of intake of inorganic phosphorus. The impaired utilization of phytin was due to its limited hydrolysis and to the incomplete absorption of hydrolyzed phytin. Vitamin D while unequivocally capable of promoting the absorption and retention of calcium and total phosphorus, did not show a clear-cut enhancing effect on the utilization of phytin. A high cereal or phytin-containing diet is believed to be an important factor in the pathogenesis of osteomalacia.

The primary purpose of this investigation was to ascertain the role of a high cereal or phytin-containing diet in the pathogenesis of osteomalacia. Numerous studies have made it clear that osteomalacia

is primarily due to vitamin D deficiency and that factors like the low calcium Chinese diet and the excess mineral drain from repeated pregnancies and prolonged lactation play contributory but important parts in making the condition especially prevalent in China. The relatively high total phosphorus content of ordinary Chinese diet has hitherto conveyed an impression of adequacy of phosphorus intake, and any deficiencies in the absorption and retention of phosphorus were regarded as secondary to vitamin D deficiency and calcium shortage. However the present work indicates that the form of phosphorus supplied is significant. The results presented confirm the observations of previous workers in animal experiments that whenever phytin constitutes a considerable proportion of the phosphorus intake, the absorption and retention of phosphorus are much less than when a similar level is administered in the form of inorganic phosphorus. This impairment of phosphorus metabolism is accompanied by a decrease of calcium absorption and retention.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Gold, C. W.: The Os-Purum Implant. A Substitute for the Autogenous Implant. *J. Bone Surg.* 1944, 26: 758.

In the author's experience with os-purum implants, the following conditions were noted:

1. All osteogenic sources about the recipient bed must be carefully preserved.
2. Complete fixation of the parts must follow implantation with os purum.
3. Complete asepsis with the Lane technique is preferred. (In many of the author's cases sulfanilamide powder was sprinkled into the wound before it was closed without any appreciable slowing in the rate of acceptance.)
4. Intramedullary fixation can be used in selected cases without complicating the result appreciably.
5. The implant should remain in its bed for six teen weeks, even if there are signs of intolerance or of foreign-body reaction. By that time it has served its purpose and can be removed.
6. The implant should be shaped to the desired size as carefully as possible. An excess amount of os purum appears to take a long time for absorption, and may produce a slight serous discharge for several months at the site of the wound. This occurred, however in a very limited number of cases. Removal of the implant, or of the excess of the implant, will not interfere with bone formation, and the wound will close promptly.
7. Os-purum implants unless under physiological stress and strain and surrounded by osteogenic tissues will be resorbed and disappear.

Details of the cases used for this report are included. The author believes that the use of os purum has its place, and that os purum constitutes a satisfactory material for the orthopedic surgeon. For the duration of the War however it appears that os purum cannot be obtained from Sweden. The supply in this country is almost exhausted. Perhaps some biochemical manufacturer may see fit to produce os purum in this country if this can be done under trade agreements.

Leriche and Pollicard pose three propositions to be fulfilled for the future of bone surgery: (1) Can one influence the formation of bone? (2) Can one influence bone resorption? (3) Can one model new ossifications? The use of Orell's especially prepared bone introduces a substance which promises to go far toward answering these three interesting questions.

ROBERT P. MORROW, M.D.

Harris, R. L.: Amputations. *J Bone Surg* 1944, 26 625.

One of the most admirable surgical chapters of the last war was written on the subject of amputation. Separation of amputees concomitant with the installation of many amputation centers in Canada, England, and the United States is a product of this war. Much of the efficacy of the modern prostheses worn by amputees today is attributed to a clearer understanding between the surgeon and the limb maker.

The author has conveniently divided amputations into two stages: (1) the field stage, which is performed at or near the zone of combat and (2) the second stage, which is performed in the zone of the interior at some amputation center.

In the field, the amputation may be performed for a grossly infected limb, the removal of an irretrievably damaged limb, a massive wound caused by shattering missiles, irreparable circulatory damage and, lastly, to save the soldier's life. The governing principles of field amputation postulated by the author are as follows: (1) save as much of the limb as possible, (2) perform judicious débridement, (3) control infection, (4) manage the stump as an open wound, (5) enhance the healing, and (6) prevent flexion deformity of the stump. Amputation should be performed at or above the line of demarcation in all limbs exhibiting circulatory incompetency. The guillotine or modified guillotine operation is the operation of choice. Skin traction should be applied early to augment healing, except in cases with highly contaminated limbs in which one must await subsidence of the infection.

In the second stage, definitive treatment of an amputation is instituted; this is possible after the wound has healed at the amputation center. The operation must achieve as its objectives: primary healing, a perfect usable stump, an optimal level of function and a stump ready for prosthetic appliances.

The author describes and recommends four types of standard amputations of the lower extremity: (1)

Syme's, (2) below the knee, (3) Stokes-Griffith and (4) midhigh amputation.

Syme's amputation is the most serviceable operation involving the foot. If any imperfections ensue in a Syme's stump they are due to failure to secure primary healing, supervening infection, or displacement of the heel flap resulting from tissue redundancy. While Syme's stump is amenable to useful prostheses in the male, it is esthetically displeasing to women as it is notoriously bulbous.

Below-the-knee amputation differs mechanically from Syme's amputation in that the weight is borne by the flaring sides of the tibial condyles. This stump yields greater usefulness if the amputation level is no longer than 7 inches and no shorter than 5 inches from the upper border of the patella. If one has no alternative, even a 3 inch stump is better than a disarticulation. Occlusion of sebaceous glands and hair follicles with circulatory disturbances may cause cutaneous infections and therefore impair weight bearing. Scrupulous attention of the stump postoperatively is tantamount to the surgical interference.

The Stokes-Griffith amputation is the operation of choice above the knee. It yields excellent weight bearing qualities. If the femoral condyles are greatly damaged or the patella with its cutaneous envelope is irretrievably injured, then it becomes mandatory that a midhigh amputation be performed. The cut end of the femur must conform to the hemisection of the patella in the Stokes-Griffith amputation.

Midhigh amputation is to be performed in cases in which the Stokes-Griffith is inadequate. Weight bearing in this stump may be equally divided between the ischial tuberosity and the distal stump. The ideal length of the stump is 11 inches from the greater trochanter. It is necessary that the skin, fascia, muscles and bone be cut at successively higher levels. The stump should be of a conical shape and devoid of redundant tissue.

Reconditioning includes the efficient use of prostheses, avoidance of infection and flexion deformity and the maintenance of balanced muscle power by physical therapy. SAMUEL L. GOVERNALE, M.D.

Bosworth D M.: The Posterior Approach to the Femur. *J Bone Surg* 1944, 26 637.

The posterior approach to the femur has been used for the following:

1. Open reduction of malunion and nonunion of fractures of the middle third of the femur.
2. Biopsy and removal of tumors in that area.
3. Femoral shortening.

A posterior midline incision is made. The linea aspera is exposed by blunt dissection. The long head of the biceps is retracted medially for the exposure of the upper third of the femur, retracted laterally for exposure of the lower third of the femur, and divided at its distal end and retracted medially for exposure of the entire femoral shaft. There has been no instance of damage to the sciatic nerve caused by this surgical approach. Bleeding of any conse-

Fig. 1. For removal of the middle three-fifths of the femur the long head of the biceps is retracted medially.

Fig. 2. For the long portion of the middle three-fifths of the femur the long head of the biceps and the sciatic nerve tract of the leg are retracted laterally.

Fig. 3. For complete exposure of the middle three-fifths of the femur the long head of the biceps is retracted medially, and, with the sciatic nerve retracted laterally.

Fig. 4. The entire middle three-fifths should never be exposed by lateral retraction of the biceps, as the sciatic nerve will be left exposed to damage. Insert: Line of incision for exposure.

sequence was encountered only when muscular attachments to the linea aspera were freed by sharp dissection. The operation is completed by suturing the

skin only, allowing the other structures to fall back into place. Excessive formation of fibrosis is thus prevented.

GEORGE L. REISS, M.D.

FRACTURES AND DISLOCATIONS

Howard J. E. Winternitz, J., Parson W. Bigham R. S., Jr. and Eisenberg, H.: Studies on Fracture Convalescence. The Influence of Diet on Post Traumatic Nitrogen Deficit Exhibited by Fracture Patients. *Bull Johns Hopkins Hosp* 1944, 75 209.

The authors present a continuation of their studies on nitrogen metabolism in patients convalescent from fractures of the large bones of the lower limbs. In their previous communication they stated that large losses of body nitrogen were incurred following such fractures and that even after nitrogen equilibrium was regained repletion of the lost nitrogen took place at a very slow rate.

In the present report the authors attempt to evaluate the role of diet, especially protein intake, in the nitrogen loss suffered by these patients. Control studies of the expected nitrogen loss were first carried out on normal healthy individuals at bed rest on a given dietary intake. The loss was found to be very small these individuals having a negative nitrogen balance of from 5 to 20 gm per day.

Following fracture, however and irrespective of the quantity of protein nitrogen in the diet, there occurred a definite loss of the nitrogenous portion of large amounts of body protein. Ingested increments of high protein food or even of amino acids did not spare the utilization of body protein. This type of reaction seemed to demand that a certain amount of endogenous protein be catabolized and that additional dietary protein beyond a certain minimum be demineralized without serving a sparing effect on the body nitrogen stores.

As convalescence proceeded the protein-catabolism phase of this process diminished and the amount of ingested protein influenced more and more the overall nitrogen balance, tending to span the body protein and bring about a positive nitrogen balance. The fact that this protein catabolic process occurred soon after injury in healthy vigorous subjects but not in all subjects, has led the authors to suggest that this process may be helpful in some way to the individual, and that a patient capable of responding to trauma with a vigorous protein catabolism is a better "surgical risk" than one who is unable to respond in this manner.

DANIEL H. LEVINTHAL, M.D.

Leavitt, D. G. and Woodward, H. W.: March Fracture. A Statistical Study of 47 Patients. *J Bone Surg.* 1944, 26 733.

March fracture is a fissure fracture due to stress which most commonly occurs in the second third or fourth metatarsal bones, but may occur elsewhere. It is not produced by a single injury or accident. The etiology is represented by a combination of external and intrinsic circumstances which weaken the fore foot. Roentgenograms made before healing begins may show no evidence of fracture. In the later stages, callus formation and a fracture line are usually found. If no treatment is given angulation displacement, and excessive callus formation may occur.

The authors discovered that many accepted concepts were disproved and that patients had serious disability which tended to be recurrent and prolonged. Many were lost to the combat unit permanently.

The authors state that their data showing a gradual onset in 52 per cent of the cases is misleading because the soldier knows the date and stage of the march at which the symptoms began.

The atavistic foot has either varus of the first metatarsal shortening of the first metatarsal or increased flexibility of the first metatarsocuneiform joint or all of these characteristics which are predisposing factors. The high incidence (50 per cent) of normal foot posture, and the presence of varying degrees of pes cavus in 32.5 per cent of instances were unexpected.

The predisposition through congenital structure of the foot, is again indicated by the bilateral march fractures and the occurrence of refracture or multiple fractures in one foot.

Since the congenital features in the so-called normal asymptomatic soldiers are not known the authors cannot properly stress their contribution to the etiology but they no doubt, are basic etiological factors in the occurrence of march fractures.

There are many predisposing factors in march fractures, some of which, it has been found may be controlled.

Difference of opinion exists as to the desirability of suppleness in the sole of the foot. For ordinary walking it seems excellent but when a heavy pack is added a more rigid sole offers protection against excessive localized bending stress.

Training is most important. Foot and general conditioning can be obtained as effectively on soft or natural ground. Combinations of training on hard and soft surfaces should be arranged to properly adjust these factors.

Initial roentgenographic examination is often negative and should be repeated. In 8.5 per cent of the patients no fracture line accompanying the callus formation was visible at any time.

At present the authors believe that early diagnosis and treatment by absolute freedom from weight bearing until soreness disappears may give the best results.

The type of treatment and the end results, reported previously in the literature have not been clearly described.

The end-results reported in this study have been poor. The authors conclude that march fracture in soldiers is more serious than other reports have indicated.

Most patients returned to light duty with their organizations while wearing unpadded plaster casts. They appeared to do little better than did those with unrecognized or late untreated fracture, or the few patients who though seen early were untreated by choice. These poor results appeared despite the fact that weight bearing in plaster is one of the accepted forms of treatment.

In all war zone and unrequited cases. If a third of the soldiers with complications in which the patient returns, the other have in a tied up or isolated condition. The patient is kept in bed for a week, the plaster is changed a plaster applied three weeks with a light bearing on the plaster. A daily bath is necessary for a couple of weeks. At the end of the plaster period, a simple bath is the duration is over two weeks warm whirlpool bath and massage treatment are given daily and continued with the light bearing until the patient appears comfortable walking and as a fact, they are gradually increased if pain is not present.

In all three reports the author would present a series of cases to the medical staff.

R. A. P. M. and R. M. D.

Dew W. A. and Wood, J. H. March Fractures, A Series of 55 Cases. *J. R. A. M. Corps* 1941 31: 332.

The author presents a series of 55 metatarsal march fractures and reports that the majority of patients failed to develop any preexisting foot pathologies. March fractures are attributed to the carrying of the full weight of the foot and marchers are more common in the lower extremities.

In most cases, the fracture is painless and the patient is able to walk. The maximum weight of the foot is usually limited at the second or third metatarsal head. As a rule, the fracture is a hairline fracture, which is able to be treated by a cast. The patient is usually asymptomatic with a little discomfort in the placement of the foot. Only a few patients of the cases necessitated hospitalization. The author states that the hospital was approximately 10 days. The out-patient group required only a few days of rehabilitation.

Local treatment in the mild cases consists of the use of a cast for seventy-two hours, a whirlpool bath, and massage and crutches under the foot bearing within pain limits. Splinting of any form is not advised because of the ongoing stiffness of the foot and increasing morbidity. The prophylactic measures advanced by the authors have met with the most high incidence of march fractures. They recommend a gradual lengthening of the march, progressive increase of heel girth, and what is most important, that the soldier march on the soft shoulders of the roads or across the hills.

SEYMOUR L. GORVATSKY, M.D.

Wilson P. R.: March Fractures: A Series of 64 Cases. *J. R. A. M. Corps* 1941 31: 157.

March fractures were described as early as 1855. By analyzing some 64 cases, the author hopes further light may be thrown on the etiology, treatment, and prevention of the condition. The present series all occurred in young soldiers undergoing a course of training at an Army physical development center. Each course at the center lasts about two months.

The essence of the author's program was graduated physical development. The patient must be taken once a week, starting with three or five miles and working up to eight miles in the last week before and in the final week there is a full on-mile march on each of two consecutive days. For the first few weeks the trainee carries no pack or rifle, but there are added to his load in the two months of training.

As a result of his study, Wilson believes that the incidence of march fracture in the present war is probably higher than for previous cases would indicate. The main factor in etiology, as it appears to be, is a poorly developed crust with poor muscle tone, (b) an unusually high ratio of rigidity to load carried, and (c) a tendency to repeat foot strain and (d) previous and repeated foot strain and (e) changes to the Army boot.

Amputation is almost never indicated early in all cases, the main advantages being an early return to full duty, counteracted by satisfactory healing and ultimate foot function, the limitation of hospitalization, and the elimination of repeated amputations of the foot and the physical and military training.

The possible prevention of the condition of march fracture is a point he is attempting to bring to the proper physical development of the foot and early attention to the condition, using special exercises to develop and strengthen the foot. Adequate care, such as vitamin and mineral should be given.

The tempo and duration of the recruit's training should be geared according to his physical standards. Furthermore, he should be allowed a few weeks to accustom himself to the training with march boots. Army boots are and accurate foot fitting at the outset is essential.

In all cases of pain in the foot following a march strain, such a measure, the possibility of march fracture should be borne in mind. The case may well be present a symptom of the foot, but if it is not being a characteristic, the patient may at first show nothing, and should be reported in all doubtful cases in two weeks.

LESLIE C. HARRISON, M.D.

ORTHOPEDICS IN GENERAL

Schwartz, R. P., Bowman, H. D., and Smith, W. R.: The Significance of Muscle Spasm in the Late Stages of Infantile Paralysis. Based on Follow-up Records. *J. Am. M. Ass.* 1941 63: 1001.

The authors review the literature and the theories regarding the behavior of the neuromuscular mechanism in the acute stage of infantile paralysis. In attempting to differentiate and evaluate muscle spasms and muscle spasm, they studied a total of 50 individuals employing action-current records as their most useful evidence. The 50 individuals studied included 10 normal subjects, 9 patients with spastic paralysis, 6 patients with infantile paralysis, 23 and miscellaneous patients 12.

The evidence collected by these action-current records indicated that during the acute stage of in-

infantile paralysis spasm is present in both weakened and normal muscles when they are stimulated by the stretch reflex. During the postacute stage this spasm diminishes and action-current records made years after the onset of this condition revealed weakness of voluntary contraction without evidence of spasm. In no instance was spasm found when a muscle failed to produce a record of reaction to voluntary movement.

It is the author's opinion that spasticity is a generalized phenomenon in the early stages of infantile paralysis and that there is no correlation between the degree of spasm and the incidence of muscle weakness or paralysis.

DANIEL H. LEVINTHAL, M.D.

Kark, W.: Foot Strain in Services. *J. R. Army Med Corps* 1944, 83: 166.

The author believes that about 1 of every 4 or 5 surgical (soldier) outpatients presents himself because of foot strain and that approximately half of these patients have mild structural deformities. The clinical picture is essentially the same whether the anatomical structure is normal or altered. He then

discusses the incidence of the common deformities and their place in the fatigue syndrome of the foot. Deformities are probably the sequelae of foot strain in a much larger proportion of cases than was considered proved in this series. It is practical to regard all cases primarily as the result of muscular fatigue from overuse and to treat them from this point of view.

The author has found that the adoption of this attitude is emphatically indicated by the almost uniform failure of boot wedges, bars, and arch supports and the patent evidence that the minor foot operations of civilian practice produce major disabilities in service personnel. Adequate foot hygiene and thorough early treatment of minor ailments and injuries are essential measures in the reduction of the incidence of foot strain. Further reduction can be achieved by more gradual and selective training, the essence of the problem being to educate muscles whatever the anatomical form of the foot. The treatment of acute and chronic foot strain is considered in three stages: absolute rest in bed, active exercises in bed, and lastly the stage of weight bearing exercises. Adequate treatment requires hospitalization for from two to six weeks. EMIL C. RONTGEN, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Duncan, G. W.: Venous Pressure as an Index of Blood Flow in the Upper Extremity. *Arch. Surg.* 944, 40-45.

In 1909 a method of determination of the rate of blood flow in the arm was described. It consisted essentially in placing the upper extremity in a plethysmograph and measuring the initial increase in volume of the limb when the venous outflow was occluded by a pressure lower than the diastolic pressure. This principle has more recently been applied to finer methods of determining the rate of blood flow in both the upper and lower extremities. Since vascular engorgement of an extremity is obvious when venous occlusion is produced, the idea suggested itself that measurement of the rate of rise in the venous pressure in one of the large veins of the forearm might be to some degree indicative of the rate of blood flow in the extremity. The author describes in detail the method used in measuring venous pressure as an index of the rate of blood flow in the upper extremity.

Venous occlusion was obtained by an ordinary blood pressure cuff, applied about the upper part of the arm. The pressure to which the cuff was raised was in all cases approximately 10 mm. of mercury below the previously measured diastolic pressure. The remainder of the experimental procedure was then carried out by two different methods. In the first the blood-pressure cuff was rapidly inflated to the desired level by means of a hand bulb while in the second the cuff was more rapidly inflated from a 15 gallon (58-liter) bottle reservoir. Tabulations were presented giving the results of the experiment with both methods. The results of the methods were similar.

These observations indicate that the rate of rise in venous pressure in the large veins of the forearm reflects to some degree the rate of blood flow in an extremity. When the vein of an extremity is suddenly occluded by a pressure lower than the diastolic pressure the arterial inflow continues. The incoming blood progressively distends the arterial, capillary and venous systems which increases the volume in the arm. The initial rapid arterial inflow represents the normal rate of inflow. Gradually this rate decreases as the pressure rises in the capillary and venous systems. The rise in pressure in the venous system, as measured in these experiments, is probably a later phase in the process than the initial increase of volume, which is used as an index in the plethysmographic methods.

The exact relationship between the results obtained by the plethysmographic methods and the results obtained in these experiments is difficult to state since different units of measurement are employed.

The author concludes that the measurement of the rate of rise in venous pressure in the large veins of the forearm following venous occlusion is at least to some extent, an index of the rate of blood flow in the extremity. Local application of heat to the hand and forearm and exercise of the muscles of the hand and forearm increase the rapidity or rise in venous pressure, while local application of cold decreases it.

HENRIET F. THURGOOD, M.D.

Sherman, R. S.: Varicose Veins; Anatomic Findings and an Operative Procedure Based upon Them. *Ann. Surg.* 1944, 120-172.

A general scheme of arrangement of the saphenous system in the thigh exists but variations are common.

The occurrence of a heretofore unrecognized location of the saphenous vein between the deep fascial layers, of a constant vein perforating the middle of Hunter's canal at about the junction of the upper and middle thirds of the thigh, and of an inconstant perforator vein connecting with the medial genicular venous plexus and the subartorial vein is described.

Although anatomic variations are common, a definite plan exists the surgical significance of this plan is emphasized and suggestions are made for what appears to be more effective operative therapy.

JOHN J. MALONEY, M.D.

Neuhof, H.: The Problem of Embolism of the Pulmonary Artery; Report of a Transcardiac Operation. *Ann. Surg.* 944, 40-452.

The author states that 88 consecutive postmortem examinations at the Mount Sinai Hospital, New York, were studied by himself and a coworker. In this study, obstruction of the pulmonary artery was the essential cause of death in cases of massive pulmonary embolization. The factors producing death were obstruction, asphyxia, and heart failure. In 26 cases, the condition developed during illness and in 62, during surgical postoperative periods. There was evidence at autopsy of previous peripheral embolization in 43 cases.

Some emboli were extremely long, with twiglike branches; others were short and curled up. Some were firm, others friable. A few were firmly adherent. The embolus was situated (1) in the outflow tract of the pulmonary artery (2) in the main trunk and (3) in one or more of the major branches or it was fragmented and distributed in the lesser branches. The author notes that the chances of encountering and removing the embolus at operation cannot be gauged in advance. The symptoms in the 88 cases were those of asphyxia, shock, syncope, or heart failure singly or in various combinations. Although the classical cases can be recognized readily the differential diagnosis from coronary thrombosis, in particular or from noncardiac lesions, in general, may

be difficult or virtually impossible. The electrocardiogram is not of decisive aid.

With regard to the topographic features alone, embolotomy would have been feasible in 33 of the 53 cases. There were no distinctive clinical features to differentiate these cases from less favorable cases. Hence, an operation always must be regarded as an exploratory one. A significant fact concerning the cases to be regarded as favorable for embolotomy was that the duration of life was short in many.

In 1938, there were collected 132 cases in which the Trendelenburg operation had been performed with a mortality rate of 93.2 per cent. Seven patients recovered. The unfavorable features are (1) an extremely high mortality (2) the requirement of a very hasty operation because of the short period of possible occlusion of the pulmonary artery (3) a too formidable operation in case of error in diagnosis, (4) an unsuccessful operation if the embolus is not of classical topography and in the typical situation, (5) the requirement of a specially trained team and (6) the limitation of operation to a rare clinical variety of pulmonary embolism.

One case report is given and the operation used is described in detail. The author states that the operative procedure is simple, reasonably safe and does not require undue haste. Special skill and practice and a special team are not needed. The suction of blood, which results in some measure of decompression of a right ventricle laboring unavailingly against the obstructing embolus is a desirable feature. However, the essential part of the operation is performed blindly and does not provide assurance that suction will engage the thrombus in the eye of the catheter. A metal tube with an appropriately hollowed end would probably be more effective in engaging and extracting the thrombus. Despite the fatal issue in the reported case, further attempts to extract a pulmonary embolus through the right ventricle appear justified. HERBERT F. THURSTON, M.D.

BLOOD TRANSFUSION

Shenkin, H. A. Cheney, R. H. Govons, S. R., Hardy, J. D., Fletcher, A. G., and Starr, I.: On the Diagnosis of Hemorrhage in Man. A Study of Extensive Bleeding in Volunteers. *Am J M Sc* 1944, 708, 421.

It is widely accepted that hemorrhage can be diagnosed by a rapid pulse and a low blood pressure. Because many patients showed none of the signs ordinarily expected after a large hemorrhage the authors are seeking to find by what means this condition can be diagnosed in patients not seen until after hemorrhage has taken place. Furthermore a project of this kind would throw light on the important question of how much blood donors should be asked to give with due regard to their safety.

Eighteen volunteers were bled approximately 500 cc and 17 were bled about a liter. Estimations of the pulse rate, blood pressure, venous pressure, cardiac output (ballistocardiograms) and hematocrit

determinations were made before and after the hemorrhage during the process of recovery and often after replacement of the blood. The technique used is described in detail.

Observations on subjects bled approximately 500 cc showed that in the supine position the average systolic blood pressure diminution was only 9 mm. of mercury immediately after the hemorrhage and there was a slight downward trend for the remaining period of observation. When standing the systolic pressure diminished 14 mm. of mercury after the hemorrhage. In supine subjects the average diastolic blood pressure did not change significantly after the hemorrhage but when the subjects stood, this pressure averaged 7 mm. less after the hemorrhage.

The average pulse rate did not change significantly after a hemorrhage of 500 cc. but when the subject was erect the average increase after hemorrhage was conspicuous and highly significant. This increase was maintained during the period of observation. The average cardiac output and stroke volume changed very little after the 500-cc. hemorrhages. Those were made only in the supine position.

After the subjects were bled approximately 1 liter 11 were observed for about one half hour or less, 5 for three hours and 1 for twenty-four hours before restoration of the blood volume. Hemodilution was followed by means of the hematocrits. In 11 cases samples were taken before and within twenty-five minutes of the cessation of bleeding; in these the reduction of corpuscle volume averaged 2 per cent. A slowly increasing dilution of blood took place after hemorrhage but the blood volume was not restored in any of the cases during the period of observation. Observations made of the blood pressure while the subjects were recumbent showed that after the minimum had passed the blood pressure increased slowly. If first seen two hours after the event the hemorrhage would never have been suspected from the blood pressure readings which were taken while the subjects lay at rest.

The pulse rate after these large hemorrhages exceeded 100 in no case except that of the subject who had had a corresponding tachycardia before the event. Slowing of the pulse was more common than acceleration. In subjects first seen after the event the authors noted that the hemorrhage could never have been diagnosed from the pulse rate. The venous pressure was estimated in 7 subjects. There was either a small diminution or no change after hemorrhage. In the absence of acute attacks the estimations of cardiac output would have provided no clear evidence of the preceding blood loss in the great majority of instances.

When the subject arose after a large hemorrhage, he could not tolerate the erect position because of faintness and dizziness and these were soon followed by collapse if he was not immediately laid flat. Two subjects bled smaller amounts in proportion were able to stand without collapse but the abnormal increase in their pulse rates on arising indicated the strain to which the circulation was sub-

jected. The acute symptoms which so many subjects experienced when they stood upright and a few when they lay recumbent, differed only in their severity. In 2 subjects who did not faint on arising, the systolic blood pressure which normally changed 5 mm. on arising fell from 10 to 30 mm. of mercury. In the 4 who became faint, the blood pressure tended to collapse as the symptoms appeared. Diastolic pressure in either position was not greatly affected.

The effect of hemorrhage on healthy men may be divided into three stages of severity. In the first stage the subject is symptom free at rest and has a pulse rate and blood pressure within normal limits, however when he arises an undue acceleration of pulse rate and some diminution of blood pressure are found. In the second stage there are still no noteworthy abnormalities as long as the subject is recumbent and at rest, but the upright position cannot be tolerated and syncope soon overwhelms him if he arises. In the third stage syncope attacks accompanied by bradycardia occur even though the subject is at rest and recumbent. These attacks seem to be of physiological and not of emotional origin.

The old concept that acute hemorrhage can be readily diagnosed by a rapid pulse and a low blood pressure is erroneous. Three things have probably contributed to the traditional viewpoint. First, a rapid pulse and low blood pressure are characteristic of rapid hemorrhage in anesthetized animals. The fact that the unanesthetized animal can stand a much larger loss of blood without undue acceleration of the pulse and diminution of blood pressure is not so widely known to clinicians. Second few clinicians have ever seen a hemorrhage in which they had any exact idea of the amount of blood lost, and so they were not in a position to criticize the common view. Third in many hospital cases hemorrhage is associated with trauma, and it is beyond dispute that rapid pulse rate and low blood pressure may be associated with shock.

Recumbent subjects may be bled to the point of collapse without exhibiting conspicuous tachycardia, and during the period of severe symptoms profound bradycardia is the rule. The blood pressure usually remains within the normal range until the symptoms of collapse begin, when it diminishes profoundly. Hemorrhages causing no signs or symptoms as long as the subjects are recumbent can be detected by having them sit or stand upright, then the symptoms described will speedily betray the abnormality.

HENRIET F. THURSTON, M.D.

Denstedt, O. F., Osborne, D. E., Stansfield, H. and Rochlin, I.: The Survival of Preserved Red Cells after Transfusion. *Anesthesiology* 944.

5 37

Fantus' idea of the blood bank in 1937 gave a tremendous impetus to the use of preserved blood. The use of preserved blood may well be regarded as one of the most important advances in medicine.

In the storage of whole blood the primary concern is the preservation of the erythrocyte. This implies

not only keeping the cell membrane intact, but also retarding the autolytic changes within the cell which impair its functional properties when it is again placed into the circulation. While the integrity of the cell membrane may be influenced by many agencies directly as for example by the action of hemolytic agents either present in or added to the blood it is now realized that hemolysis during storage is brought about largely as a result of autolytic changes within the cell. As soon as blood is removed from the body the cell membrane undergoes marked changes in permeability especially in the cold. Potassium ions diffuse out of the cell while sodium ions enter from the plasma. Complex organic phosphates in the cell undergo autolytic hydrolysis with the liberation of phosphate. Glucose breaks down to lactic acid and other intermediates. Some of the products of autolysis, including phosphate, do not pass through the membrane readily at lower temperatures. Hence as the osmotic pressure gradually increases, water enters the cell which causes it to swell and ultimately to burst.

Individual bloods differ in regard to cell stability, i.e., rate of hemolysis during storage and preservative solutions may differ greatly in their cell stabilizing qualities. Sodium-citrate solution alone although still fairly widely used, is among the poorest of preservatives. In this solution hemolysis usually becomes visible after about the fifth day and the majority of the red cells undergo irreversible changes by the tenth day. The addition of dextrose to citrate, on the other hand, greatly improves its preservative qualities. In isotonic citrate-dextrose the rates of autolytic change and of cell swelling are much reduced. Blood may be kept in this mixture for six weeks and sometimes for two months with negligible breakdown of cells. The stability of the red cells is influenced also by the proportion of diluent used. With isotonic citrate-dextrose the maximum stability appears to be obtained with most bloods in the dilution of one volume of blood to one half volume of diluent. In phosphate-buffered citrate-dextrose blood may be diluted much further and may be stored at higher temperature, e.g., at 8° or 10° C., without impairment of the stability of the cell.

Since there is no in vitro test for the vital capacity of red cells the only means of testing the influence of storage and of preservative mixtures is to transfuse the cells and follow their survival in the recipient.

The survival of erythrocytes after transfusion has been variously estimated as from thirty to eighty days, depending on the method employed. Some may remain in the circulation for one hundred and thirty days or even longer.

Cell survival is greatly prolonged when preservative mixtures containing dextrose are employed. Dextrose appears not only to stabilize the cell membrane but also to retard autolytic changes during storage, hence it may be considered a true preservative.

To test the merits of two preservative mixtures, i.e., a modified DeGowin's citrate-dextrose, and a buffered citrate-dextrose 35 transfusions were per-

formed, with bloods ranging from strictly fresh to samples stored up to fifty-seven days. All subjects were serologically negative and were in good health from a nutritional point of view. The cell survival was studied by Wiener's method.

Both the buffered and the unbuffered preservative mixtures used in this study give very satisfactory preservation of the erythrocytes. The buffered solution tends to reduce the packing of cells on sedimentation and hence facilitates resuspension. It also is the more effective in retarding autolytic changes during storage, notably the breakdown of labile organic phosphate compounds. Despite these merits however the red-cell survival after transfusion was not noticeably superior with the buffered solutions. While some bloods keep better than others, cells stored up to eighteen days may be considered equivalent to fresh cells, as a rule. No toxicity develops in blood stored up to two months, i.e. long after the majority of the cells have lost their functional qualities.

The relatively rapid disappearance of other elements, such as white cells, platelets, prothrombin, complement and hemopoietic properties from blood during storage presents no serious problem since when fresh blood is required it is usually obtainable from the blood bank. For secondary anemias and especially in acute hemorrhage blood stored for three weeks and even longer is efficacious. Under war conditions, and particularly in areas within bombing range, it is necessary to maintain large supplies of blood and plasma. While it is desirable to keep within the three-week storage limit, there should be no hesitation in using specimens up to a month old in emergencies. Numerous instances have been reported in the present war in which month-old blood has been used with good results.

Under the conditions of the present study red cells can be stored for six weeks and in some instances two months with less than 1 per cent hemolysis.

Janeway C. A.: Clinical Use of Products of Human Plasma Fractionation. Albumin in Shock and Hypoproteinemia; Gamma Globulin in Measles. *J. Am. M. Ass.* 1944, 126: 674.

By the application of large scale methods of fractionation (developed in the Department of Physical Chemistry of the Harvard Medical School Boston) to pooled human plasma from blood collected by the American Red Cross concentrated human serum albumin gamma globulin antibodies isohemagglutinins, fibrin films, and fibrin foam with thrombin have been made available for clinical use.

Concentrated human serum albumin as dispensed in the standard Army and Navy package provides a compact, stable solution which is ready for immediate use in the emergency treatment of shock.

The use of albumin in cases of shock due to hemorrhage, trauma and burns results in an increase in blood volume, hemodilution and clinical improvement. The blood volume is increased in these conditions by approximately the amount to be expected

from measurements of its osmotic pressure (18 cc. per gram of albumin).

In the presence of severe dehydration albumin must be supplemented with fluids in order to obtain the maximum therapeutic effect.

Albumin is an extremely safe blood derivative and it can be administered very rapidly without reaction even after periods of heating at temperatures of 50 C. for as long as one hundred days.

Albumin can be used to correct hypoproteinemia if sufficiently large amounts are used.

In the nephritic syndrome the injection of albumin is followed by a definite increase in proteinuria but does not regularly result in a diuresis.

Gamma globulin antibodies (fraction II of Cohn Strong, Oncley, Hughes and Armstrong) contain most of the antibodies of pooled normal human plasma in 15 fold concentration over the original plasma. Gamma globulin antibodies are the safest and most effective agent available for the prevention and modification of measles by passive immunization. For this purpose the injection should be given preferably on the fifth day after exposure. At this time a dose of from 0.1 to 0.075 cc. per pound will completely protect most susceptible individuals while one of from 0.015 to 0.02 cc. per pound will result in mild measles in most cases. The mild measles in patients receiving globulin is similar to that previously observed in patients immunized with convalescent serum or placental extract. Complications were noted in 3 of 400 cases of measles in immunized children but it occurred in patients in whom the globulin failed to modify the disease. Reactions were noted in only 1.7 per cent of 1,843 intramuscular injections. One half of these consisted of local soreness and most of the remainder of fever. Only one anaphylactoid reaction occurred which was probably due to an idiosyncrasy. Gamma globulin is very effective in controlling the spread and severity of measles in pediatric wards but does not appear to be effective in the control of chickenpox. J. M. MORA, M.D.

Ingraham, F. D. and Bailey, O. T.: Clinical Use of Products of Human Plasma Fractionation: The Use of Products of Fibrinogen and Thrombin in Surgery. *J. Am. M. Ass.* 1944, 126: 680.

The preparation of purified human fibrinogen and thrombin has made possible new materials for use in surgery. The solutions of the proteins may be employed and a variety of products may be prepared by combining them under different conditions. Of these, fibrin foam with thrombin is a new absorbable hemostatic agent prepared from fibrinogen and thrombin of human blood plasma.

Extensive clinical use of fibrin foam with thrombin in neurosurgical operations has shown it to control oozing from the dura from beneath bone flaps and from the cerebral tissues as well as from the dural sinuses and large veins. It is not recommended for brisk arterial hemorrhage.

The tissue reaction to fibrin foam with thrombin is minimal and negligible from the clinical standpoint.

In this respect, as well as in regard to its availability ease of manipulation and adaptability fibrin foam with thrombin is much superior to muscle. It is prepared wholly from materials of human origin.

This hemostatic agent can be used with advantage in certain procedures by the general surgeon. It is also effective in controlling hemorrhage in patients with hemophilia.

A limited use has been made of solutions of fibrinogen and thrombin in certain special situations in which it is desirable to form a clot *in situ*.

Fibrin film is a homogeneous sheet prepared from human fibrinogen and thrombin. It has proved effective in the repair of dural defects and the prevention of meningocerebral adhesions.

J. M. MORA, M.D.

Jacobson, S. D. and Smyth, C. J.: Gelatin as a Substitute for Plasma; Observations on its Administration to Human Beings. *Arch. Int. Med.* 944, 74 254

This study on human subjects was designed to obtain information regarding the value of gelatin as a plasma substitute. Fifty six injections of gelatin were given to 45 subjects in amounts ranging between 450 cc. to 1,000 cc. the rate of injection varying from 56 cc. to 10.2 cc. per minute. Gelatin solution was also given to 3 moribund patients and their tissues were subsequently examined histologically.

The effect of the gelatin solution on the plasma volume was measured in 12 subjects. The immediate average increase in plasma volume was found to be 58 per cent of the volume of gelatin solution administered after four hours it was 70 per cent and after twenty four hours 46 per cent. The disappearance of gelatin from the blood stream was studied in 12 patients and the amount recovered in the urine of 8 of these patients was measured. The blood-stream concentration of gelatin decreased progressively from an initial value of 0.6 gm. per 100 cc. to less than 0.1 gm. in twenty four hours. Throughout the period studied the elimination of gelatin proceeded at a more rapid rate than the fall in plasma volume, 87 per cent of the gelatin having disappeared from the blood stream in twenty four hours while the average plasma volume increase at this time was 46 per cent of the volume of the gelatin solution injected. Approximately 46 per cent of the gelatin injected was recovered from the urine in the first four hours and an additional 30 per cent was recovered in the next twenty hours. The excretion of gelatin in the second twenty four hour period was

slight so that the average total amount recovered in forty-eight hours was 81.3 per cent of the amount injected.

No significant changes in the levels of blood urea nitrogen and amino acids were found during the period of observation. The increase in erythrocyte sedimentation rate was uniformly marked and was found to parallel the gelatin concentration in the serum, being approximately normal at the end of twenty four hours. In 3 moribund patients who received repeated injections of gelatin and whose tissues were later examined histologically no pathological changes were noted which might be attributed to the gelatin, nor was any evidence observed of retention of the gelatin in the tissues. Elevation of the blood pressure and clinical improvement were observed in each of 50 patients who were given gelatin solution for shock therapy. No untoward reactions were observed during or following any of the infusions.

JOHN L. LOMQUIST, M.D.

RETICULOENDOTHELIAL SYSTEM

Bersack, S. R.: Hodgkin's Disease. *J. Am. Med. Ass.* 944 26 025

The patient who is the subject of this report was encountered in a study of 353 cases of Hodgkin's disease. The unusual features of this case and the rarity of cutaneous Hodgkin's disease are deemed sufficient justification for the publication of this report.

The case of cutaneous Hodgkin's disease reported illustrates a rapid terminal spread through the blood stream and the additional unusual feature of ulceration of the Hodgkin's skin lesions. The fact that no malignant cell could be found in the microscopic examination of the early skin nodules caused by blood-stream spread is in favor of a virus etiology of Hodgkin's disease. The hematogenous dissemination must have been mediated through the humoral content of the blood. The only alternative would be to incriminate the few lymphocytes found in the initial stage of a new focus. They might possibly be the vectors of the virus.

The theory of a virus etiology of Hodgkin's disease is an attractive one in that it will explain the early clinical features of an inflammatory nature and also the later development into a seemingly autonomous neoplastic disease. This theory deserves further clinical and experimental study. It may be worth while to attempt transmission experiments with blood derived from a patient who as in the present instance, is exhibiting blood-stream spread.

JOHN E. KIRKPATRICK, M.D.

SURGICAL TECHNIQUE

WAR SURGERY

Bell, R. C.: Analysis of 259 Flying Bomb Casualties. *Brit. M. J.* 1944, 2: 689

This report relates the experiences of a small emergency hospital during the flying bomb raids on Britain. During this bombing period, 222 casualties on an out-patient basis and 259 in patients were treated. The greatest number of casualties on one admission reached 26 and of these 12 had to be taken to the operating room. Injuries due to flying glass occurred most frequently and exceeded more than half of the total number of casualties. Most of these injuries were above the nipple and usually caused severe damage to the face, neck or eyes. In 10 cases the globe of the eye was completely destroyed. Flying glass rarely pierced the deep fascia but usually lay in hundreds of small pieces under the skin and subcutaneous fat.

Early careful surgical toilet of these wounds under anesthesia seems to be contraindicated especially if debridement lasts for more than one hour. It is recommended that this type of casualty be permitted to recuperate thoroughly from shock before surgery is begun. Penetrating wounds from bomb splinters were few because the fragments were small, the coefficient of friction high and the velocity low. On rare occasions the bomb fragments were large, and in these instances severe surgical damage was produced. Masonry injuries became more common when people learned to take cover. However the crush syndrome with edema of the injured part, anuria, and uremia was not encountered, because of the increased speed and efficiency of the rescue squads. Blast injuries affecting the lungs were manifested by pain in the chest, dyspnea, and bloody sputum. Blast injuries of the eyes caused a variety of effects, from a feeling of pressure and smarting in the eyes to perforation of the globe, hyphema, and subconjunctival hemorrhage. Blast injuries of the head were usually of the cerebral concussion variety. Burns from flying bombs were

The dosage varies considerably with each patient. The authors recommend a first injection of 0.5 mgm. per pound of body weight, less 30 mgm. and increase of each injection by 10 mgm. Each injection should be prolonged for a period of from one to one and one half minutes. It is advisable that the full two-minute period elapse between additional injections.

Finally curare is to be used with caution prior to endoscopy in patients with a marked diminution in tidal exchange. Cyanosis with convulsions occurred in 3 cases of this type, while difficulty in breathing manifested itself in 2 additional cases of this type.

Curare relaxes the striated musculature and may be useful in troublesome endoscopies. On the other hand since it is difficult to determine the exact dosage for each patient and since the effects of the drug are so unpredictable, curare may not be used for endoscopy with safety. To obtain relaxation for endoscopic procedures other measures are preferred, such as adequate preoperative medication with the barbiturates by mouth and with morphine and atropine by subcutaneous or intravenous injection or the intravenous use of barbiturates.

The curare preparation used in this report is marketed under the name "Intocostin."

BENJAMIN GOLDMAN, M.D.

Felmus, L. B., Woods, C. C., and Spreng, D. H., J.: Pilonidal Cysts. *Arch. Surg.* 1944, 49: 316.

Various theories concerning the cause of pilonidal cysts are discussed as well as the high rate of delayed healing and the recurrence of pilonidal infection following operation. In view of the fact that recurrence of infection may result from failure to dissect out all the finer ramifications of the sinus, from persistence of infection or bacterial contamination due to the proximity of the anus, from the poor blood supply following the formation of fibrous scar tissue or from a combination of these factors, the authors have succeeded in reducing the rate of recurrence by careful attempts to eliminate all these possible causes.

At the Oliver General Hospital, Augusta, Georgia, (except in cases with the formation of abscesses) the procedure has been excision en bloc, with primary closure of the resulting wound. Prior to operation the patients are instructed to take Sitz baths several times daily. The sacrococcygeal area is prepared the day before and on the day of operation and as little healthy tissue is removed as is consistent with complete excision of the sinuses and cyst. The general direction and depth of the tracts are determined by probing at the onset. The open wound is then irrigated and dusted with sulfanilamide powder. With careful attention to hemostasis and the obliteration of dead spaces, closure is effected with non-absorbable sutures. Undercutting of the skin has rarely been necessary. A point is made of accurate apposition of the cutaneous edges, followed by the release of retained blood from the wound and covering of the wound with a strip of sulfanilamide gauze

TABLE I—RESULTS OF TREATMENT

	Per cent of cases
Healed by primary union	65
Healed by secondary union after primary closure	34
Recurrences	1

The average stay in the hospital, including two weeks of reconditioning, was fifty-one and seven-tenths days.

and a pressure dressing. Stress is placed on cleanliness of the lower part of the back and the avoidance of fecal contamination of the wound.

In cases of recurrent sinus or persistent infection of an imperfectly healed wound, reoperation is performed exactly as outlined and as often as deemed necessary after a few weeks and after the usual cleansing Sitz baths.

The table above summarizes the results in the first 100 patients so treated.

Only 2 patients of the 54 who were admitted to the hospital without previous operation had recurrences. Follow-up inquiries indicate that about 5 per cent have been rehospitalized after discharge from the hospital. The authors believe that the problem of pilonidal cysts and their delayed healing is one of infection and of wound healing rather than of true recurrence of the pilonidal sinuses.

JOHN L. LINDEQUIST, M.D.

Graham, D. P.: Rapid Replacement of Fluid in Hemorrhage and Shock. *Brit. M. J.* 1944, 2: 633.

Many authors are of the opinion that the rapid introduction of fluids into the circulatory system of the body causes acute dilatation of the right side of the heart. In a series of battle casualties in the Mediterranean theater of war fluids were infused rapidly and observations were made of any ill effects which this procedure might have on the heart and circulation in the lungs. The patients were received from on half hour to twenty two hours after being wounded. All were suffering from physical fatigue, a degree of anxiety neurosis, dehydration, and from the effects of severe trauma and blood loss.

All patients received 3,000 units of antitank serum intramuscularly and 2½ gm. of sulfanilamide by mouth. Routine resuscitation measures were carried out. The fluids were infused under pressure by attaching a Higginson syringe to the air inlet.

Ten case histories are given in detail. The temperature, pulse, respirations, blood pressure, hemoglobin, and general condition of the patients were checked and the findings were considered typical of those in a larger number of patients treated.

In cases in which the blood loss is estimated to be severe (about 2 liters) replacement cannot be too speedy. It is estimated that the patients in this series lost an average of 54 liters of blood. The incidence of reactions was less than in cases in which fluid was given slowly and in small quantities. When sufficient time had elapsed to allow the hemoglobin to fall considerably there were no signs of overloading of the circulation. In cases in which there was

embarrassment of the cardiovascular system as a result of toxemia damage to the thoracic contents or continued internal hemorrhage rapid transfusion was harmful. Cases of trauma to the limbs, with gross hemorrhage showed an excellent response to this rapid technique.

The points of contrast between shock and the effects of hemorrhage are so numerous that the assumed identity of these conditions is no longer defended.

The case histories showed that these patients suffered mainly from posthemorrhagic hypotension combined with a certain degree of shock. If the shock is not too profound the heart is capable of dealing adequately with large volumes of infused fluid and the vascular bed is capable of retaining this added fluid for use by the circulation.

Infusions at the rate of 143 cc. a minute in no way embarrassed the cardiac mechanism. Patients with toxemia (peritonitis) and wounds of the lung developed pulmonary edema after mass infusion. Patients with peripheral trauma and hemorrhage without sepsis did not develop pulmonary edema.

The author recommends that an estimate be made of the loss of blood volume in the battle casualties who require blood transfusion. Hemoglobin readings should be made before and after the infusion of plasma. The estimated loss of fluid should be replaced rapidly with the aid of pressure to prevent the development of post traumatic hypotension into true shock.

RICHARD J. BENNETT JR., M.D.

Guthrie, D. and Schimmel I: Drainage in Thyroidectomy *Surgery* 1944, 16 725

The necessity of drainage after thyroidectomy seems to depend on the kind of suture material used. All of the wounds sutured with catgut had to be drained, while 82 per cent of those sutured with silk could be closed. However since the use of cotton the authors have drained only 8 of 580 thyroidectomy wounds.

All the drains are placed under the skin flaps and not in the goiter bed. The wound is closed with clips and No. 80 cotton is used on the skin flap. All dissection must be sharp. The authors suture the sternothyroid muscle in the midline and if necessary, to the base of the remnant. To prevent flap oozing they employ a special notched rubber sponge over the flap. The details of the technique should be read in the original article.

FRED S. MODERER, M.D.

Kraybill, W. G.: Total Disruption of Surgical Wounds of the Abdominal Wall, with Reference to Plasma Proteinemia and Plasma Ascorbic Acid. *Am. J. Surg.* 1944, 66 220.

The disruption of abdominal wounds is a distressing complication of abdominal surgery. Investigation has emphasized the importance of the protein metabolism and the role of vitamin C in wound healing. The deleterious influence of foreign bodies in the form of reactive suture material has also been established clinically and experimentally.

In a series of 375 cases of abdominal section there were 7 (1.8 per cent) with total disruption of the wound. These were studied with special reference to proteinemia, detectable ascorbic acid in the plasma and the fate of the catgut sutures.

In 6 of the 7 cases the plasma protein was below the lower limit of normal—6.5 mgm. per cent, only 1 patient had this level. In none of the cases was there detectable ascorbic acid in the plasma at the time of total disruption. In 5 cases the administration of 150 mgm. of ascorbic acid a day was inadequate to produce a detectable quantity in the plasma within a week.

It has been established that reactive suture material plays an inhibitory role in wound healing. Wire has been shown to give the least reaction, while cotton silk, plastigut, nylon and catgut show increasing reactivity in the order given.

In addition to the diminution of plasma protein and ascorbic acid, the disrupting forces of coughing and excessive distention are probably contributing factors. In this series the factors of age, carcinoma type of incision, drainage through the wound, infection and general nutrition were also unquestionably contributory to the total abdominal wound disruption.

SAMUEL KAHN, M.D.

Helfrick, F. W. and Abelson, N. M.: Intravenous Feeding of a Complete Diet in a Child. *J. Pediatr.* S. Louis, 1944 25 400.

A five-month-old white infant with Hirschsprung's disease, complicated by a digestive upset and upper respiratory infection developed a most extreme picture of marasmus which gave every indication of an impending fatal termination. The baby was given a complete intravenous feeding for five days with fats, carbohydrate and amino acids in proportions and quantities recommended in a normal infant's diet. There was a prompt dramatic improvement in the nutrition which permitted eventual successful treatment of the Hirschsprung's disease with proctigmine. This is the first case on record of complete feeding by vein alone for a significant period of time.

The details of the intravenous feeding were as follows:

The preparations available for intravenous administration were 50 per cent glucose solution, a 10 per cent solution of amino acids (amigen) and a 10 per cent emulsion of fat. The fat emulsion consisted of olive oil and lecithin in a 2:1 ratio suspended in water the total lipid concentration being 10 per cent. This material was passed through a dairy homogenizer and was subsequently given sixty minutes of irradiation to cause further dispersion of the fat particles.

The parenteral feeding was designed to provide 58 per cent of the calories (300 calories) from carbohydrate, 12 per cent (60 calories) from amino acids and 30 per cent (160 calories) from fat. This required the daily administration of 150 cc. of 50 per cent glucose solution, 150 cc. of 10 per cent amino acids and 180 cc. of 10 per cent fat emulsion. An

additional 120 cc. of normal saline solution was given, to make a total fluid intake of 600 cc. per day.

To administer these preparations a continuous intravenous drip apparatus was used. A 20-gauge needle with a stylet was tied in place in the left saphenous vein just anterior to the medial malleolus in the left ankle. The remainder of the apparatus consisted of an open-top graduated cylinder, connected by rubber tubing to a Murphy drip and from there to a metal attachment which could be inserted into the needle. The solutions, in the quantities determined were introduced into the apparatus on the following schedule: 12 midnight, 60 cc. of 10 per cent fat emulsion, 3 a.m. a mixture of 50 cc. of 50 per cent glucose, 50 cc. of 10 per cent amino acids and 30 cc. of normal saline solution. At 8 a.m. and at 4 p.m. these solutions were repeated in the same order.

The rate of flow was adjusted so that the administration of one solution was finished at about the time the next one was due, but if any solution ran in completely before the time was up the apparatus was disconnected and the stylet used to close the needle. Later the solutions were permitted to run in faster so that the drip was intentionally interrupted for periods as long as four hours. The use of the stylet permitted the interruption of the infusion at any time, so that the baby could be moved, turned, or weighed, and the apparatus cleaned and sterilized.

The chief purpose in introducing the solutions separately instead of mixing them all together was to avoid having the fat stand for any length of time in contact with saline solution, since solutions of electrolytes neutralize the charge of fat emulsions and cause, in time, some coalescence of the fat particles into larger aggregates.

EDMUND E. ARNHEIM, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Pope, C. H., and Perkins, R. M.: Differences in the Patterns of Bites of Venomous and of Harmless Snakes. *Arch. Surg.* 944, 49 33

The literature on snake poisoning is misleading in stating that a pit viper makes only one or two large punctures when it bites. In contrast to the several rows of small ones made by a harmless snake. The reason for this is said to lie in a difference between the behavior of the two types of snakes. I.e. the pit viper merely stabs with its pair of long fangs, whereas the harmless snake actually bites. It is demonstrated in this article that pit vipers of the United States bite as effectively as most innocuous snakes in no sense do they merely stab. The bite pattern of the pit viper though not simple, can be recognized. Moreover a careful study of the bite may reveal the approximate location of the pocket of venom, the size of the snake, and even its generic identity.

In dealing with any physical injury the first step is to make an exact analysis of it. In the case of snake bite, one must first determine whether one is

treating actual snake poisoning or merely superficial scratches and pricks of a harmless snake. Physicians who report cases of poisoning should include diagrams of all marks made by teeth and fangs and thus help in the accumulation of data on bite patterns. Directions for the treatment of snake bite should explain the true difference between the bite patterns of harmless and venomous snakes and explain how interference by clothing will invariably modify both.

Converse, J. M., and Robb-Smith, A.H.T.: The Healing of Surface Cutaneous Wounds: Its Analogy with the Healing of Superficial Burns. *Ann. Surg.* 1044, 120 873.

Interest in the healing of cutaneous wounds produced by the removal of skin grafts was aroused by the fact that the wounds of superficial burns appeared to present a similar process of healing. Brown and McDowell made the same observation, and later Cannon and Cope used skin graft donor areas to test the effect of coagulants on epithelial growth.

Four hundred and sixty nine skin-graft donor areas were studied. These skin grafts were removed for use in plastic operations and for the covering of raw areas created by burns or trauma. Three types of skin grafts were employed: thin Thiersch grafts, thicker split (intermediate) grafts which were removed with the Blair skin graft knife and skin grafts of varying thickness (from 0.010 to 0.042 inches) cut with Padgett's dermatome. The donor sites used were the medial aspect of the arm, the abdomen, the back, and the thigh. A few grafts were removed from other regions of the body.

The routine postoperative treatment of the donor areas was as follows: gauze soaked in 1/1000 adrenalin solution and large saline packs were held with pressure against the bleeding donor area. Then strips of fine-meshed vaselined gauze impregnated with sulfanilamide powder were applied to the wound and covered with gauze, cotton and a pressure bandage firmly anchored with adhesive. The dressings over the skin-graft donor areas were removed when the latter were healed. The approximate healing time of these donor areas was observed the dressing being removed when the vaselined gauze could be easily detached from the new epithelial surface.

It is obvious that accurate comparative data are difficult to obtain because the thickness of the graft, which is cut with the dermatome, varies greatly with the thickness of the cement which is employed to produce adherence of the skin to the dermatome drum, because of individual variations in the characteristics of the skin of the different patients, and because of variations of the age and general condition of the patients. However it is believed that observations in a sufficient number of cases (469) have permitted the following conclusions:

In the study of superficial burns, a comparative study of 500 donor areas of partial-thickness skin grafts was made. The following facts were noted:

1. The quality of the repair was roughly proportional to the rapidity of healing

2. The rapidity of healing was dependent upon (a) the thickness of the graft removed (Thiersch from six to ten days intermediate, fourteen days full-thickness, from twenty-one to fifty-eight days), (b) the thickness of the skin of the donor site and (c) the presence or absence of infection

3. Epithelial healing originates from the epithelial elements in the dermis, hair follicles sebaceous glands, and sweat ducts. The number of these elements decreases in the depth of the dermis and so healing is slow

4. In slow healing areas abnormal fibrous tissue is laid down in excessive amounts. The epithelium formed is of poor quality

5. Contraction following healing is appreciable in areas from which grafts have been cut near the base of the dermis. In deep dermal burns and in mixed burns, such a contraction has been observed and is called "interland contraction"

From 101 burned patients, 63 biopsy specimens were removed. The extent of the anatomic destruction of the burn wounds and the mode of healing of these wounds were observed.

An anatomic classification of burns is proposed.

A description of the clinical and pathological aspects of superficial burns is given

The authors point out that there may be need for skin grafting in certain superficial burns particularly on the dorsum of the hand and around the joints in ectropion of the lids in distortion of the features of the face because of tightness produced by interland contraction, or because of poor quality of the healed skin.

JOHN E. KIRKPATRICK, M.D.

Feinman, M. H.: Tropical Ulcer. *N. Eng. J. M.* 1944, 331: 578

Feinman presents a clinical discussion of the disease variously known as *ulcus tropicus*, tropical sloughing phagedena, and Naga sore. It consists of an acute or chronic skin lesion of uncertain etiology but closely related to the presence of spirochetes and fusiform bacilli, and characterized by an irregular or rounded appearance indurated edges an excavated base, a dirty greenish-gray sloughing membrane and red granulation tissue in the base and walls. These ulcers usually occur on broken or injured skin. Therefore, all troops should be cautioned about this so that they may promptly apply a bactericide and first-aid dressing in an effort to prevent ulcer formation at these points.

Medical officers should learn to recognize these ulcers early. They should not experiment with the easily available sulfonamide drugs or ointments, gentian violet or Frazier's solution to see what will happen but should proceed directly to treat them vigorously with the intravenous injection of mapharsen and the local application of sulfanilamide or sulfadiazine powder as their appearance or bacteriology may direct. After the ulcers have become

clean occlusive vaseline dressings should be applied and changed infrequently

Mapharsen can and should be made easily available to forward echelons and treatment should be instituted in the early stages of the ulcer. In this way patients can remain ambulatory, with no loss of work or fighting and no hospitalization.

J. M. MORA, M.D.

Southworth, J. L.: The Effects of Sulfanilamide Locally Implanted in Clean Wounds. *Am. J. Surg.* 1944, 66: 345

A study was undertaken to determine the effect of local sulfanilamide implantation in clean wounds. Patients with bilateral inguinal hernias were selected as subjects. Through 2 separate inguinal incisions a routine bilateral hernioplasty was performed at one sitting. The layers were sewed with interrupted catgut stitches. Sulfanilamide powder was placed in one side and omitted in the other. Five grams of the drug were used; they were spread evenly throughout the layers of the wound. In 11 patients unsterile crystalline sulfanilamide was used and in 14 sterile drug was employed. To obtain further controls no drug was used on either side in 12 cases.

Careful observation of these cases leads to the conclusion that sulfanilamide in hernioplasty wounds frequently produces hemorrhage into the wound and surrounding tissues and sometimes produces an increased induration of the wound but it has no effect on healing as determined by physical examination

SAMUEL KAHN, M.D.

Pressman, R. S., and Bender, I. B.: The Effect of Sulfonamide Compounds on Transient Bacteriemia Following the Extraction of Teeth. *Sulfanilamide. Arch. Int. M.,* 1944, 74: 346.

In 30 control subjects and 30 sulfonamide treated patients cultures taken immediately after the extraction of teeth were positive for bacteriemia in 83.3 per cent and 76.7 per cent, respectively. Cultures made ten minutes after the extractions (of from 3 to 10 teeth) showed a more significant difference—13.3 per cent positive for the treated group as compared with 33.3 per cent for the control group.

The bacteriostasis produced by sulfanilamide appears to have not only a delayed quantitative but also an immediate qualitative effect. Aerobically sulfanilamide in vitro exerts no bacteriostasis but, anaerobically it has a marked bacteriostatic effect. Since the organisms circulating in the blood stream are few a sensitive medium must be used to detect their presence.

WALTER H. NADLER, M.D.

Welch, H., Putnam, L. E., Randall, W. A., and Herwick, R. P.: Penicillin. *N. J. Am. M. Ass.* 1944, 126: 1024.

In a recent issue of *Science* it was reported that gonorrhea had been successfully treated with single injections of 100,000 units of commercial penicillin incorporated in a beeswax peanut oil base. The authors have had an opportunity to investigate the

properties of so-called penicillin X sometimes referred to as factor X, or allopenicillin.

Preliminary studies indicate that penicillin X is three to five times more effective than commercial penicillin in protecting mice against 10,000-unit lethal doses of pneumococcus type I.

On the basis of the increased activity of this new preparation against certain organisms in comparison with commercial penicillin it appeared desirable to determine the effect of this preparation on the gonococcus. Accordingly 68 patients with gonorrhea most of whom were sulfonamide-resistant, were treated with a single intramuscular injection of 25,000 units of penicillin X. The group consisted of 35 males and 33 females. Approximately 94 per cent of those treated were cured.

For comparative purposes a group of 31 males and 27 females were treated with a single intramuscular injection of 25,000 units of commercial penicillin. Based on the same criterion 37 patients, or approximately 63 per cent, of those treated were cured.

It is of interest that 3 of the patients not cured with commercial penicillin were cured by a subsequent single injection of 25,000 units of penicillin X.

Although the number of cases reported is small, it further work substantiates the fact that a large proportion of cases of gonorrhea can be cured with a single intramuscular injection of penicillin X, the public health control of this disease, which has been maternally affected by the use of commercial penicillin will be further facilitated.

JOHN E. KIRKPATRICK, M.D.

Peck, F. B. Penicillin; with Special Reference to Its Use in Infections Complicating Diabetes. *Am J M Sc.* 1944, 208 58

The efficacy of penicillin in the treatment of certain types of pyogenic infections together with its remarkable lack of toxicity suggested that the drug might be particularly useful in the management of some of the more localized and generalized coccic infections so frequently encountered in association with diabetes mellitus.

In contrast to the sulfonamides which have been ineffective in the local infections, penicillin is remarkably efficacious. It cannot be expected to restore dead tissue, but it appears of especial value in the infectious type of gangrene when the circulation is intact. In carbuncles and other infections caused by staphylococci results have been particularly striking.

The author employed penicillin locally in 15 cases of diabetes complicated by infection and obtained a rapid and sometimes dramatic response in some of the early cases of carbuncle following the injection of penicillin directly into the infected tissues. The solutions used for this purpose have ranged from 100 to 1,000 per cubic centimeter of saline solution. In no instance has he observed any tendency toward a deleterious effect on carbohydrate tolerance, nor has penicillin administration necessitated larger doses of insulin. The presence of infection notoriously in-

creases the insulin requirement of the diabetic, but in none of the cases described was there any unusual difficulty the patients responding particularly well.

Use of penicillin does not relieve the clinician of the necessity of taking all the other precautions necessary for proper treatment of infections. Drainage must be established surgically since the mere administration of penicillin not only is wasteful but may not be adequate. It is essential to determine the causative organism.

JOSEPH K. NARAY, M.D.

Sophian, L. H.: The Use of Penicillin in Topical Application. *Am J M Sc.* 1944, 208 577

Because of the shortage of penicillin a technique for the extraction of penicillin from the urine of patients under treatment for syphilis, gonorrhea, and septic infections was developed by the author. It was found practical and inexpensive and it yielded from 30 to 40 per cent of the antibiotic substance administered. A considerable number of animal and clinical trials demonstrated that the reclaimed penicillin was nontoxic and nonpyrogenic when used parenterally. Dosages as high as 2,000,000 units a week were administered intramuscularly with excellent clinical results, which differed in no way from therapy with commercial penicillin.

The availability of the material has encouraged the author to make certain observations concerning the use and desirability of topical applications. When consideration is given to the difficulty and expense of maintaining over a period of many days or weeks a high penicillin concentration by parenteral administration topical applications, when practicable, offer a suitable alternative. The author found it possible to reach local levels of penicillin activity by topical administration far in excess of the highest ranges he has maintained by intravenous and intramuscular use, namely between 0.7 and 0.9 units per cubic centimeter of blood, achieved by continuous introduction at the rate of 20,000 units per hour. There are many bacteria including some strains of staphylococci, which are resistant to low penicillin concentrations or even to the high levels noted, but they are susceptible at still higher levels. For the control of such infections, penicillin may be applied topically or by both parenteral and topical routes.

Penicillin incorporated in a suitable ointment, together with a wetting agent, penetrates agar sufficiently to cause inhibition of the bacillus subtilis at a depth of 16 mm. Although it does not demonstrably penetrate through a skin layer in vitro, penicillin in such an ointment base has strikingly effective value in acute and chronic pyogenic infections of the skin and subcutaneous tissues, particularly in syccosis barbae, infected superficial wounds, and furunculosis.

The appearance of a zone of infection under treatment with the ointment is characterized by hyperemia and arrest of suppuration. In an uncomplicated situation like a furuncle the first change is seen after twenty-four hours in a lessening of the peripheral edema and a reduction in tension of the lesion.

Early furuncles resolve in from four to six days but suppurating ones will go on to evacuation. Chronic pyogenic infections respond slowly and develop a considerable zone of hyperemia when the ointment is applied for extended periods. The granulation tissue growth is accelerated and the surface becomes engorged.

The author recommends a penicillin ointment in which aerosol serves as a vanishing cream base.

JOSEPH K. NARAT M.D.

Murphy F. D., La Boccetta A. C. and Lockwood, J. S.: The Treatment of Human Anthrax with Penicillin. *J Am M Ass* 1944 136 948.

The authors for the first time used penicillin in the treatment of 3 cases of uncomplicated cutaneous human anthrax without bacteremia. Exceedingly prompt and excellent clinical response was observed in every instance. The 3 cases are briefly reported.

The clinical response was paralleled by the disappearance of the bacillus anthracis from the lesion. It was found that twenty four hours after the administration of 100,000 units of penicillin the smear was still positive and the culture was negative but in forty-eight hours both the smear and culture were negative. In vitro studies of the strain of 1 case revealed the bacillus anthracis to be 100 times less sensitive to penicillin than a strain of the staphylococcus aureus.

It appears from these studies that a total of 100,000 units of penicillin is the minimum effective dose in the uncomplicated case of cutaneous anthrax. At least a total of from 100,000 to 400,000 units at the rate of 100,000 units per twenty four hours should be given to the average adult. Continuous intravenous infusion is probably the most efficient method of administration although intramuscular injections every two or three hours lead to just as good results.

ANESTHESIA

Crooke, A. C. Morris, C. J. O. R., and Bowler R. G.: General Anesthesia in Shock. *Brit M J*, 1944, 2: 683

The high mortality rate from surgery on patients in shock may be ascribed to hemorrhage to the operative manipulations, or to the anesthesia. In the present study the pulse, respiratory rate, blood pressure, plasma volume, hemoglobin and electrocardiogram were observed in a series of 16 patients with normal initial values of these factors. Changes in blood pressure were produced by variations in the depth or type of anesthesia but were not found to be related to surgical manipulation. Changes in blood pressure occurred independently of any change in plasma volume and hemoglobin level. Changes in blood pressure were not reflected in alterations in the serial electrocardiograms. Cardiographic irregularities were never constant.

Patients in traumatic shock with significant alterations in plasma volume suffered a marked fall in

Fig. 1 Effect of nitrous oxide, oxygen, and ether on blood pressure, hemoglobin and dye concentration.

blood pressure due to the anesthetic. Ether or ether and chloroform caused the most profound fall. Sodium pentothal acted in a manner similar to ether. However cyclopropane and oxygen usually increased the blood pressure except in the severely shocked patient.

B. G. P. SHATTUCK M.D.

Lull C. B. and Hingson R. A.: An Evaluation of Continuous Caudal Analgesia. *N York State J M* 1944, 44: 3337

The authors of this article attempt to give the medical profession an unbiased opinion of the value of continuous caudal analgesia for the relief of pain. Team work between the anesthetist and the obstetrician is essential for the proper accomplishment of the technique. The physiology of labor and delivery observed by the midwife and interpreted in our existing textbooks on obstetrics has been completely altered since the inception of successful continuous caudal analgesia. The first stage of labor is dramatically shortened, and the third stage of labor is shortened and simplified so that in many instances hemorrhage in this stage will be unbelievably small. There is a reduction in postdelivery convalescence time with a rapid involution of the uterus, a return of the cervix to its prepregnant state, and a regaining of good muscular tone by the perineum.

Stress was laid on the number of anomalies which were found in the sacra of the 241 cadavers dissected. 22 of all the sacra studied exhibited openings in the roof and more than 11 per cent had a bony defect at the superior pole. Eight per cent had bony defects in the inferior pole. Five tenths, or 1 per cent, of the female sacra and 2 per cent of the male sacra presented no roof at all. In 55 per cent it was found anatomically that caudal needles could not be introduced because of osseous obliteration of the sacral canal. An understanding of the anatomical features involved is important to the successful introduction of a caudal needle. When the sacral

hiatus cannot be felt, the patient is considered unsuited for caudal analgesia. In routine cases however when special medical indications such as tuberculosis or heart disease are presented, these patients are roentgenographed by the Bishop modification of the Moloy technique for a special sacral study. This is considered one of the most important supplementary techniques that have been added to the caudal analgesia technique since its introduction.

Among more than 3,000 personally observed and managed obstetrical patients not a single case was found in which a complete block of the eleventh and twelfth thoracic nerves was not accompanied by the total relief of the abdominal pains of labor. There was not a single case found in which well established contractions of the uterus did not continue if the level of analgesia was not permitted to rise above the tenth thoracic segment. Therefore the authors have confirmed the natural anatomic dissociation between the motor and sensory components and uterine nerves.

Pudendal nerve block can be accomplished by a single caudal dose, which produces a sensory block of the nerve supply to the cervix and eradicates the intense, agonizing crescendo of pain in the lower back.

In from 40 to 60 per cent of the patients there was no significant change in the force, frequency or duration of the pattern of uterine motility under caudal analgesia. The second type of uterine response occurs in from 20 to 35 per cent of the patients and in these there was a constant diminution in uterine tone with increased amplitude of uterine contraction. These labors, like those in the first group, progress rapidly and are terminated successfully. In the third group of patients, the uterine tone may be increased and there is a diminution in the amplitude of the contraction. These responses are frequently associated with a high level of ascent of the analgesia to the point of the fifth or sixth thoracic segment. In these patients the labor pains are ineffectual and the progress of labor is retarded.

It is the consensus of the authors that metycaine (1.5 per cent) though clinically no more toxic than procaine, is definitely more potent. Other reasons are presented for the preference of the former.

The complications associated with this technique were presented, 36,000 deliveries under this method being reviewed.

Researches include the use of continuous caudal analgesia in surgical cases peripheral vasospastic disease, thrombophlebitis, peripheral arterial embolism, scleritis, pruritus ani, and traumatism of the lower extremities. This method has dramatically reduced both systolic and diastolic blood pressures in patients suffering from hypertension. In some patients the reduced blood pressure remained so for as long as two days up to three weeks. This method has given encouraging results in a series of more than 40 eclamptic patients. At the present time the authors are attempting to evaluate the difference, if any, between fractional spinal and continuous

caudal anesthesia. It is their opinion that either one of these methods is eminently satisfactory and that there is very little difference between the two. A group of tables in the article shows the age group, the parity, the presentation of the fetus, the method of delivery, the blood pressure record, and the length of labor in a series of 963 cases. The failures of the method are enumerated, they occurred in 120 patients or 12.5 per cent of the total. Three maternal deaths are listed in this group, none of which is attributed to the use of the continuous caudal analgesia.

The incidence of complications and the contraindications indicate that this is still a technique to be performed by specialists in the hospital.

MARY KARP, M.D.

McClellan, G. S., and Williams, E. L.: Comparative Analysis of Drugs in Continuous Caudal Analgesia. *Am. J. Obst.* 1944, 48, 617.

Pontocaine (0.1 per cent) with epinephrine (1 to 500,000) is a safe and satisfactory caudal analgesic agent. Pontocaine (0.35 per cent) and pontocaine (0.1 per cent) without epinephrine have been unsatisfactory.

Two drugs have been used with equal effectiveness: metycaine and pontocaine. The duration of effective analgesia was of some interest. Metycaine injected in 20-cc. or 30-cc. amounts was effective for between thirty and forty five minutes. Pontocaine (0.35 per cent) injected in the same volume produced analgesia for between forty five minutes and one hour and pontocaine (0.1 per cent) plus epinephrine was effective for as long as one and one-half hours. Caudal analgesia has great possibilities for use in obstetrics and in surgery of the pelvis. It is possible to relieve pains of labor during the first stage and to produce anesthesia for delivery. The baby's respiration is established immediately and no resuscitation is necessary.

The method is one to be used only by persons familiar with local and regional anesthesia and aware of the dangers involved. Caudal analgesia is unsatisfactory for patients with breech presentations.

Since the mechanism of labor is altered with the use of continuous caudal analgesia, no one should attempt to use this method unless he is familiar with the techniques of rotation of the fetal head and the use of the obstetric forceps.

EDWARD L. CORSELL, M.D.

Roman-Vega, D. A., and Adriani, J.: Clinical Experiences with 2-Methyl-Amino-Heptane as a Vasopressor Substance for Spinal Anesthesia: A Preliminary Study. *Current Res. Anesth.* 9:4, 23, 248.

This preliminary report describes an attempt to determine the clinical value of the aliphatic type of vasopressor drugs in spinal anesthesia. It comprises the experience with 2-methyl-amino-heptane in a series of 100 patients undergoing operation under spinal anesthesia.

The drug is a clear colorless volatile liquid which is slightly soluble in water. At the present time it is available only for investigational use and is designated as EA 1 hydrochloride. It causes a rise in both the systolic and diastolic pressures, an increase in pulse pressure, and stimulation of the heart with improvement of its contractions. Dilatation of the pupils, piloerection and other manifestations of sympathetic stimulation, bronchial dilatation and decreased renal volume follow its administration. Its toxicity is low; nausea and vomiting are notably absent.

In each of the 100 cases EA 1 proved to be an effective vasopressor and successfully combated the hypotension of spinal anesthesia. The average effective dose varied between 75 and 100 mgm. When given intramuscularly the effective dose varied from 10 to 50 mgm. It is suggested that if the intravenous route is used, the drug be diluted with saline solution or distilled water (equal parts). In no case did the diastolic pressure fall with the administration of this drug, and in this aspect EA 1 differed from ephedrine. A rise in pulse rate occurred in only 6 per cent of the patients; but 16 per cent had an increase in respiratory rate, 15 per cent had pupillary dilatation which persisted for about thirty minutes, and 5 per cent had nausea and vomiting. There seemed to be excessive capillary bleeding in 3 per cent of the cases. The response was noted within three minutes if the drug was used intramuscularly and within one minute if used intravenously. The drug was felt worthy of further clinical study as a vasopressor substance for combating the hypotension of spinal anesthesia.

MARY KARY M.D.

Holly J. D.: Intravenous Anesthesia in Children.
South. M. J. 1944 37 631

Up to the present time it has been the consensus that pentothal sodium is a poor agent for intravenous use in children: first because of the difficulty of venipuncture, and second, because of the poor tolerance of children to barbiturates. There is no essential difference in the kind of drug given in childhood and in later life, and the question, "When does pediatrics end?" is still a muted problem. A discussion of the drugs used for children demonstrates the similarity of drugs used in the child and to the adult and proves that if drugs are used carefully they can be administered at any age.

The author has found from clinical experience that children tolerate pentothal sodium as well as adults.

The history of intravenous anesthesia is reviewed from the use of chloral hydrate in 1874 to the present administration of barbiturates. The effects of the drug pentothal sodium on the systems of the body are mentioned. A 2.5 per cent solution is prepared and the administration performed by means of equipment consisting of one three-way valve to which is attached a piece of rubber tubing 8 inches long. On the end of the tube is a Luer glass tip to which tip is attached an intravenous needle of 1/4 inch

length and of 22 to 24 gauge, beveled and sharp-pointed.

The veins in the antecubital fossa are usually selected also the wrist veins or the great saphenous vein anterior to the internal malleolus.

Premedication for children up to five years of age consists of atropine sulfate (gr. 1 to 1/50th) given thirty minutes before operation for children over five years of age nembutal (gr. 1 to 1/34) given one hour before operation and atropine sulfate (gr. 1 to 1/50) given thirty minutes before operation.

The technique of administration is described in detail. Fractional amounts of the agent are given as the need for depth presents itself.

Indications for the drug are enumerated and include any type of operation except bronchoscopy. The more severe the illness the greater is the indication for the drug. It can be used in acute shock and hemorrhage. If you can get into a vein you can administer pentothal as an anesthetic agent for the same surgical procedures that are performed in adults. It is contraindicated in inflammations that encroach on the trachea, neck, and posterior pharyngeal wall and in operations that involve the skin only.

There are 2 diagrams of the anesthesia equipment and 12 case records in the original article. The advantages of the drug are summarized and include its rapid induction, comparatively good relaxation, economical use and safety.

MARY KARY M.D.

Large, A. and Heinbecker, P.: Refrigeration in Clinical Surgery. *Ann. Surg.* 1944, 120 707.

The purpose of this article was to discuss the effects of cooling and the effects of asphyxia produced by the application of a tourniquet also to present cases in which a form of treatment was employed which was in harmony with the implications of established physiological principles.

Within physiological limits the velocity of most biological processes varies directly with the temperature. Cellular activity almost completely stops at temperatures close to freezing and the conduction in a nerve trunk fails at or below certain critical temperature levels (from 25 to 30 C. in warm blooded animals). Refrigeration of an extremity abolishes pain and decreases the blood and lymph flow. Inhibition of the healing of wounds during refrigeration has been shown to occur.

The effect of the tourniquet on the progress of infection varies with the duration of the period of ischemia. If a tourniquet is applied tightly enough to a limb proximal to a gangrenous or affected area the obliteration of vascular and lymphatic channels at the level of constriction will prevent the absorption of toxins and bacteria from the involved region into the general circulation. This beneficial effect will continue as long as the tourniquet is in place.

The survival of a tightly constricted limb is prolonged greatly by refrigeration of the part. The benefit of refrigeration with the application of a tourniquet below the proposed level of amputation

of a limb has included loss of sensation and elimination of absorption of noxious agents from the part the further advantage of elimination of interference with wound healing and of spread of infection is also assured.

The management of critically ill patients with gangrenous extremities frequently involves the control of toxemia of infection of anemia, and of derangements in metabolism. Six cases are presented in which gangrene of one or both feet was associated with infection and toxemia. The patients were operated on without mortality and without interference with subsequent wound healing. It was believed justifiable, therefore, to advocate the use of the method. The detail of the technique used was described. Refrigeration was not used in any case unless the patient's condition was so poor due to severe infection and absorption from the gangrenous part, that the ordinary methods of treatment seemed dangerous.

SURGICAL INSTRUMENTS AND APPARATUS

Kulowski, J. French, A. M., and Erickson, H. R.: *Aire Lite. A New Plastic Medium of Clinical Immobilization.* *Am J Surg* 944 66 315

Methods of immobilization form an interesting chapter in the history of clinical surgery. Modern methods received their impetus in 1834 when Sue tin's "starched apparatus" first appeared. Plaster of Paris bandage was invented by Matthysen in 1852. The excellent results obtained with the latter medium induced surgeons to overlook some of its disadvantages. The main disadvantages are its relatively heavy weight and bulk, its poor penetrability to the x rays, the general untidiness attending its application, wearing and removal, the occasional trickiness of its setting characteristics due to the qualitative differences that exist between the various grades of plaster, the poor ventilation and its poor resistance to moisture with a tendency to absorb moisture of all kinds, which results in irritation of the skin, discomfort to the patient, and softening of the plaster cast itself. Recent improvements in the plaster-of-Paris bandages and splints and in the plaster technique have overcome some of these disadvantages. Substitutes for plaster have been introduced, however, none has been widely accepted.

The present article contains an interesting discussion regarding Aire Lite. The principle of this type of immobilization was introduced some years ago when Roger Anderson made use of a plastic fabrication in the form of a dry open-meshed, flexible bandage, which could be applied to the body and then sprayed with a volatile setting liquid to form a rigid supporting structure. He succeeded in applying this principle for clinical purposes. Aire Lite is a stockinette form of bandage made by loosely knitting a yarn composed of a mixture of cellulose acetate and a regenerated cellulose rayon. This knitted bandage is processed to control shrinkage, setting, and drying characteristics. When in place, the band-

age is sprayed with a solvent mixture composed of a combination of volatile liquids with acetone as one of the active ingredients which initiates setting and drying until it becomes rigid.

The bandage is then unchanged in its chemical composition but its physical characteristics have been altered radically. The loosely knitted loops of yarn which previously gave great flexibility to the bandage now function as rigid strut members and make a strong open meshed supporting medium. This medium is mechanically efficient, very light in weight, resistant to moisture, nonresistant to x rays, and comfortable to the patient.

The present report is based on a series of 136 patients upon whom 200 plastic casts and miscellaneous apparatus made of Aire-Lite were employed. The authors have classified the cases for which Aire Lite was used: there were 86 fractures among which simple and compound injuries were evenly divided. In 22 cases Aire Lite was used as primary fixation at, and subsequent to, onset of treatment. Seventeen simple fractures and 1 compound fracture thus treated were acute. 4 of these needed manipulative reduction and fixation under anesthesia. The bones injured involved the hand in 5 instances, the ankle in 3, the lower radius in 3, and the sternum, the clavicle, shaft of the tibia and fibula, the head of the radius, the carpal scaphoid, and the body of the scapula in 1 case each.

In 64 fractures Aire-Lite was used subsequent to plaster or other methods of fixation which had been previously instituted as an alternative (secondary fixation) apparatus. Of these, 22 were simple fractures which had been present from several days, with little or no callus formation to variable stages of convalescence when Aire Lite fixation was employed. These comprised 10 simple fractures of small and irregular bones of the extremities and vertebral bodies, 4 of the lower radius, and 8 of the long bones. Forty-two compound fractures were secondarily immobilized by Aire Lite, 36 of these were severe. The vast majority involved the long bones and showed variable degrees of bony dissolution and osteomyelitis, with little or no evidence of wound healing or bony regeneration at the time fixation was begun.

Fifty miscellaneous orthopedic conditions included diseased static or mechanical conditions, and congenital anomalies and post-traumatic conditions of the locomotor system other than fractures for which immobilization was desirable.

The pathological lesions included hematogenous pyogenic osteomyelitis, tuberculosis, arthritis, and osteochondritis.

Among the static or mechanical conditions, lumbosacral low back pain and internal derangement of the knee joint were prominent.

The residual deformities included in this group were neurogenic, arthrogenic, and myostic in origin. One instance of bilateral congenital clubfoot was treated. In contrast to the group of fracture cases, the most of these miscellaneous cases were primarily fixed with Aire Lite.

Aire Lite cannot be expected to replace plaster. The use of Aire Lite fixation in acute fractures is not wholly practicable because of the time element involved; therefore, its use remains optional with the surgeon. Aire Lite can be used effectively as a cast, splint or other form of apparatus in a wide variety of orthopedic conditions. Instead of the primary use of plaster. The same alternative use of Aire Lite fixation in the convalescent stages of both simple and compound fractures has also been established.

Since Aire Lite is a synthetic plastic product of various inherent characteristics its use demands a definite technique. Atmospheric conditions may influence its behavior in practice and interfere with uniformity of its setting and drying. There is a reactive time lag between the bandage and the solvent as a cementing agent. Another problem is the variable tendency it has toward shrinkage and creepage which must be anticipated and guarded against by strictly observing a proper technique and keeping the patient under observation especially for the first twenty-four hours after a cast has been applied.

A study of the characteristics of Aire Lite brings out the following points:

1. An unhurried attitude and technique with calm and deliberate work is essential, and by all means gentle handling of the bandage.

2. There should be no stretching or pulling of the bandage into place because such tension results in

undue subsequent shrinkage when setting and drying have occurred. In order to go around prominent curves the bandage must be pleated, folded or cut partially or completely at that point and another section properly overlapped and directed must be begun.

3. There should be no molding or handling of the wetted bandage as prescribed for plaster since subsequent gelatinization and loss of porosity would result after the bandage had hardened. This technique requires smooth gentle pressure and stroking efforts toward adherence, with care to secure overlapping edges which require additional cementing fluid.

Aire Lite has some disadvantages but also great advantages. From the surgeon's standpoint the greatest drawback to Aire Lite is the longer period of time it takes to set and become rigid. To remedy this disadvantage improved methods of fabrication and technique are needed. Among the advantages of Aire Lite may be mentioned the following: the light weight, ventilation, resistance to moisture, nonresistance to x rays, general neatness attending its use and its acceptability to the patient—these are distinct advantages over plaster. At this particular time the advantages of Aire Lite accruing from its inherent resistance to moisture are noted under naval and similar sea going conditions. From the angle of air transport the light weight of Aire-Lite is no less important.

MATTHIAS J. SEIFERT, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Kautz, F. G., and Schwartz, L.: Intraocular Calcium Shadows; Choroid Ossification. *Radial* 27 944, 43 486

The authors give a rather comprehensive review of the literature dealing with the roentgen demonstration of calcium shadows in the eyeball. It appears from this review that although intraocular calcifications are often suspected on clinical examination and proved by subsequent dissection of the enucleated eye, their roentgen visualization is rare.

Twining and Shanks distinguish four groups of intraocular calcium shadows: (1) calcification of the lens, (2) ossification of the vitreous, (3) calcified atheroma of the carotid and ophthalmic arteries and (4) a shrunken calcified globe. According to Duke-Elder bony cataract is fairly common in the late stages of a complicated cataract. It is also a well established fact that the internal aspect of the choroid often forms the site of bone metaplasia. Samuels goes so far as to describe three types of choroid ossification: (1) plates of solid bone (2) thick shells and (3) spicules of bone.

The presence of choroid ossification is usually suggested by the history and physical examination. Blindness, cataract, and the demonstration of a hard intraocular mass in an atrophic bulb are signs strongly in favor of ossification as contrasted to glaucoma, sympathetic panophthalmitis, or tumor. Roentgen study helps to establish the diagnosis beyond doubt.

The authors found on the basis of their own material as well as that collected from the literature, that the roentgen findings of choroid calcification are rather typical. Usually there is a shrunken eyeball, a large central area of which is occupied by a well delineated fairly regular ovoid, circular or semi-circular dense (although not strictly homogeneous) calcium shadow. Sometimes the shadow assumes the shape of a ring a few millimeters thick. In a few instances metallic foreign bodies have been observed near the calcium deposits.

Anatomically these shadows correspond to the bell-like ossification of the choroid and of the lens. The smaller densities are the result of the extent of the choroid throughout the eyeball and occasionally of the invasion of the cornea.

The differential diagnosis of choroid ossification includes opaque and semiopaque foreign bodies, vascular calcifications phleboliths, orbital angioma, osteoma, and superimposed endocranial calcifications. Pfeiffer has also observed calcium deposits in congenital retinoblastoma in children.

From the technical standpoint the authors recommend that three methods be used for the roentgen visualization of intraocular calcifications: (1) the posteroanterior projection of the orbit, which offers the clearest view (2) the lateral projection as it is used

for the routine localization of foreign bodies and (3) the "bone free" projection, which permits a view of only the anterior two-thirds of the eyeball. The use of planigraphy and orbitography with air may still improve the roentgen demonstration.

Seven cases are reported by the authors in brief résumés and illustrated with typical roentgenograms. Several other cases have been seen in the past ten years but they have not been recorded. In most instances there was a history of foreign-body injury to the eye with subsequent infection and gradual loss of sight. Pain occurred only in the acute and subacute stages of infection. The patients eventually became accustomed to their condition and in only a few instances was enucleation of the eye performed.

A bibliography of 31 articles is appended.

T. LARCOMA, M.D.

Reinberg, S. A.: X-ray Diagnosis in Gunshot Wounds of the Abdominal Cavity and Its Significance in Field Surgery. *Brit. J. Radiol.* 1944 7 291

The author reports that on the battlefield, casualties with wounds of the abdominal cavity are transported to the x-ray department direct from the field, usually in the first twenty-four hours and often within a few hours of the injury. The vast majority arrive in comfortable transport, sometimes by plane.

They are examined in two positions: are not removed from the stretcher and are never made to stand. During the acute stage of their condition, no contrast substance is given internally, but shock is no contraindication to roentgenographic investigation. No x-ray examination of the abdominal cavity is considered complete unless the chest and pelvis are also examined, and if circumstances demand it, also the neck and shoulder girdle. Conversely with a wound of the chest and pelvis even when there are no special clinical indications the abdominal cavity is examined.

In the author's series of cases the vast majority of the patients had penetrating wounds. Perforating wounds were fewer and tangential wounds were rare. Shrapnel wounds were three and one-half times as frequent as bullet wounds, and fragments of artillery shells were found four times more commonly than fragments of grenades or mines. Of the bullets, the great majority were sharp-pointed and came from rifles and machine guns. The author had only 2 examples of revolver bullet wounds. Blunt-nosed bullets discharged by automatic hand weapons were frequently encountered. So far the author has seen none of the spherical shrapnel bullets that played such an important part in the last war.

In half of the cases of penetrating abdominal wounds the entry was in the lower part of the chest, usually at the level of the eighth to tenth ribs,

although sometimes higher. The entry wound was found in the anterior abdominal wall in one fifth of the cases. It is important to note that in two-fifths of all the cases the entry wound for a bullet penetrated the abdominal cavity was in the region of the pelvis.

It is difficult to decide the nature of the missile until a ray examination has been made. This is all the more important since shrapnel wounds have a much more difficult clinical course and a worse prognosis than bullet wounds. Shrapnel has a much greater tendency to pull fragments of soiled clothing into the tissues and thereby expose the patient to the risk of infection.

It is most difficult to locate foreign bodies in the abdominal cavity. The consequences of a penetrating wound are more important than its nature or its location. Roentgenological examination is undertaken primarily with the view of ascertaining the state of the abdominal cavity and its contents. The most important abdominal injury is a penetrating wound with perforation of the gastrointestinal tract. Interest centers chiefly on those clinical diagnostic signs associated with the escape of gas or fluid from the viscera into the abdominal cavity. Although the roentgenographic recognition of large amounts of gas is a relatively simple matter the demonstration of minute amounts requires exceptional technical skill and knowledge. Large amounts of gas can be demonstrated with the patient placed in any position but when small amounts are suspected the lateral view is indicated. This can be obtained with the patient on his back or on his side. With the patient on his back, quite small quantities of gas can be detected immediately above the liver dullness the so-called antehepatic pneumoperitoneum. This is the most natural position for the majority of cases but undoubtedly the most satisfactory and most desirable view is that taken with the patient lying on the left side. In this position the most minute amount of gas can be detected. This is the so-called extrahepatic pneumoperitoneum. In the majority of cases the patient was immediately subjected to a laparotomy in the course of which the diagnosis was invariably confirmed. In many cases there were so few clinical signs pointing to the presence of intestinal damage that no surgeon would have considered an operation if the presence of gas had not been demonstrated. The pneumoperitoneum is sometimes even more reliable than the visual examination at the time of operation. Of equal importance were the cases in which roentgenological examination proved to be negative in respect to pneumoperitoneum. Many cases were clinically so complex and difficult that only the radiologist's negative report prevented an operation and subsequent uneventful recovery confirmed these findings. There were occasions when a negative roentgenographic diagnosis of pneumoperitoneum was not confirmed by subsequent events. It must be noted that only about 55

per cent of cases of perforated gastric and duodenal ulcers produce a pneumoperitoneum.

The roentgenological investigation of liquid in the abdominal cavity is much more difficult than the demonstration of gas. The nature of liquid in the abdominal cavity cannot be determined roentgenologically, but it is clear that fluid found roentgenographically during the first few hours after an abdominal wound obviously is likely to be blood and thus this is an important sign of a penetrating wound. The nature of damage to solid internal organs cannot as yet be determined. Only superficial and border defects of the liver tissue can be detected. In the case of hemorrhage into the liver it is possible to demonstrate a total enlargement of the whole organ.

Because of the invariable practice of roentgenographic examination of the chest in cases of abdominal trauma, unsuspected conditions are sometimes brought to light and many of these are not demonstrated clinically.

As far as it is possible full roentgenographic facilities must be brought as near as practicable to the locality where abdominal injuries are likely to be found. It is essential that the interval between the time of injury and the institution of proper treatment should be reduced to a minimum.

HAROLD C. OCHSNER, M.D.

Peters, M. V.: Radiation Therapy of Carcinoma of the Breast. *Canad. M. Assn. J.* 1944, 51: 335.

In this article the author reports his results in radiation therapy of breast lesions during a two-year period evaluating the effect of 400 kv. on the various stages of malignant mammary lesions.

The statistical data show the relationship between age and survival, between rate of growth and survival and between the duration of the disease and survival. In addition the table which accompanies the article shows the most frequent sites of metastases.

The lesions of the breast were divided into three stages.

Stage I lesions consisted of those which were entirely within the mammary gland without fixation or evidence of extension. In this group the five year survival rate was raised from the average of 65 to 75 per cent chiefly by the use of postoperative irradiation.

Stage II malignancies included the lesions which were surgically difficult to remove and those in which a high degree of malignancy had been determined by the use of Lee and Stubenbird's table of clinical index of malignancy. In this group the five year survival rate was raised from 15 to 30 per cent.

Stage III carcinomas were the ones which were beyond help and in which radiation therapy could offer only palliative aid.

The author believes that preoperative irradiation particularly in stage II lesions would materially influence the end results. R. A. BRADY, M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Davidson, L. S. P: *Nutrition and Diet in War Time*.
Edinburgh M J 1944, 51: 430.

A considerable section of the population of Britain was living before the present war on a diet which was inadequate to meet the optimal demands for growth and the maintenance of health. It is also clear that the dietary deficiency was mainly qualitative rather than quantitative. In other words, the caloric value of the diet was seldom at fault, the deficiency was essentially of vitamins, minerals, and to a less extent, of first-class proteins.

In arriving at any conclusion regarding the effect of war on the diet of the nation as a whole, two questions will have to be answered:

1. Have the restrictions imposed by war produced an undesirable reduction in the quality or quantity of the diet consumed by people whose intake of food was formerly unrestricted by economic circumstances?

2. Have the wartime food measures produced an improvement or a further deterioration in the diet of that section of the population which even before the war was unable to buy sufficient of the right kind of food to supply its nutritive requirements?

The second question is the more important, as the individuals in this section of the population had no nutritive "slack" to take up and any further deterioration in their diet would necessarily have led to such a serious increase in ill health that the morale and efficiency of the home front would have been undermined.

Since two-thirds of Britain's food was imported it was obvious that a serious reduction in the food supply would result as soon as the stocks of imported foods were used up unless drastic measures were instituted both to augment the supply of ships and to increase the production of certain foods, the balance being imported according to a plan designed on a scientific basis. The country was faced not only with a deficiency of such basic products as meat, fats, and cereals, but also of important protective foods such as the dairy products, fruit, and vegetables. The British Government decided that it was essential, in the first place to secure the caloric value of the nation's diet, and accordingly took steps to increase greatly the home production of food and to import the remaining requirements according to a scientific plan. An agricultural policy, which primarily concentrated on the production of cereals and potatoes was adopted. By 1943 the production of wheat, barley and oats in tons had been increased by 80 per cent and of potatoes 95 per cent. Since milk cannot be satisfactorily replaced by any food and cannot be imported from a distance in a fresh state, the maintenance of or

even an increase in, milk production was accepted as another essential feature of the wartime agricultural policy. This could be accomplished only by carefully controlling the plowing-up policy on dairy farms and by giving dairy cattle the highest priority in the issue of concentrated feeding stuffs. The production of milk has been maintained at the pre-war level, despite the great reduction of grass land. The consumption of liquid milk is actually 34 per cent higher in 1944 than in 1938, because the diversion of liquid milk to manufacturing purposes has been prohibited. The third essential feature of the food policy was an increased home production of green and yellow vegetables. By 1943 an increase of 33 per cent over the prewar consumption had been secured by a combination of methods including stabilization of prices, subsidies for the professional grower and propaganda directed toward the private individual with a garden or allotment.

The first priority on shipping had obviously to be reserved for wheat which is easily transported and stored and which constitutes the most suitable food for maintaining the caloric needs of the nation. The Government's decision to keep flour bread, and potatoes unrationed as long as was humanly possible was undoubtedly sound both on administrative grounds and because it ensured that no one needed to go hungry for want of energy-giving foods. The second priority was fats which have more than twice the energy value of carbohydrates, are valuable sources of fat-soluble vitamins, and take up relatively small amounts of cargo space. The third priority for importation was cheese, which is a particularly condensed form of food valuable for its fat, calcium, and protein content. The latter aspect was of especial importance because of the decision to reduce greatly the importation of meat. Meat is a foodstuff which is bulky and which requires special refrigeration facilities. The importation of fruit had to be almost completely abandoned because of its bulk and poor keeping qualities. With the object of increasing the carrying capacity of the ships available for the transport of food the bulk of the foodstuffs was, whenever possible, reduced by the processes of compression and dehydration (e. g. milk, eggs, fruit juice, and, recently meat) and by deboning the carcasses of animals. By increasing the extraction rate of flour from 70 per cent (white flour) to 85 per cent (National wheat meal flour) a greater yield of flour is obtained from a given weight of grain. The introduction of the 85 per cent extraction flour in 1943 not only saved several hundred thousand tons of shipping space annually but secured the vitamin B requirements of the nation and greatly augmented its supplies of iron and valuable vegetable protein.

Although the wartime diet is monotonous, it is adequate in so far as calories and protein are con-

ceded and it is superior to the prewar diets in respect to the minerals, calcium and iron and the vitamins of the B complex. Only in respect to vitamins A and C is there any reason to suspect its adequacy.

If the outbreak of the war it was apparent that particular attention should be given to certain classes of individuals whose demands for certain factors were enhanced because of their requirements for growth, pregnancy or illness. The nutritional factors of particular importance for these categories are first-class protein, calcium and vitamins A and C, a deficiency of which constituted a potential danger in the wartime diets. To prevent the development or minimize the effects of such deficiencies, the Government not merely undertook a campaign of increased production, as outlined but introduced special measures which gave a priority supply of food and vitamin supplements to these persons whose needs were greatest:

1. Vitamin A (as cod liver oil or halibut liver capsules), vitamin C (as orange juice, rose-hip syrup and black currant juice), and milk to pregnant and nursing mothers, infants and children under 5.

2. An extra half meat ration to expectant and nursing mothers.

3. Milk and meals in school for children of school age.

4. The setting up of industrial canteens and British restaurants where workers can obtain meals cheaply and in addition to the ration.

5. The provision of extra cheese rations to agricultural workers and miners who are unable to obtain meals at canteens.

6. Extra rations and special priorities to invalids and persons on special diets, e.g.

(a) Double meat and fat ration and extra cheese and milk ration to diabetics.

(b) Special milk allowance to patients with gastric diseases and patients suffering from tuberculosis.

(c) Extra meat rations to patients suffering from steatorrhea and hepatitis.

(d) Special priorities of milk, eggs and fish to hospitals, etc.

7. Compulsory fortification of foodstuffs, viz.

(a) Addition of vitamins A and D to margarine.

(b) Introduction of calcium into National Flour.

The effect of five years of wartime diet on the national health showed no decrease in the general economic efficiency. Despite the housing, transport and black-out difficulties, the productivity per head of population in Great Britain is stated to be the highest in the world.

The consensus of opinion among school teachers, social workers, school medical officers, and research workers who have carried out nutritional surveys is that the health of the children of Britain in 1944 is satisfactory. The Parliamentary Secretary to

the Ministry of Food stated in August, 1944 that a recent investigation of some 30,000 adolescent and adult males revealed no evidence of any loss of weight or unsatisfactory growth.

Despite the dangers of overcrowding and reduced ventilation due to the black-out, and shelter life the incidence of the majority of the common infectious diseases, with the exception of venereal diseases and tuberculosis, is actually less in 1944 than before the war.

The birth rate has increased and the death rate for the country as a whole has decreased.

Research workers, social workers and experienced clinicians alike are all agreed that frank deficiency diseases such as scurvy, beriberi and pellagra are as rare today in Great Britain after five years of war as they were in prewar days. Large-scale surveys of the incidence of anemia, as carried out by the writer as well as by others in Great Britain show that by and large the position in regard to iron deficiency anemia is satisfactory.

Flourid rickets is as rare today as it was in the immediate prewar period.

A survey carried out by M. Mellanby and H. Connolly on London County Council school children in 1943 under conditions of control and clinical assessment similar to those used in the same area in 1929 showed the percentage of teeth with perfect or nearly perfect structure was more than twice as great in 1943 as in 1929 while the percentage of very defectively formed teeth was reduced by approximately half.

The more fortunate members of society whose diet was formerly unrestricted by economic circumstances have had a reduction in their intake of many of the essential nutrients as a result of the war but the evidence adduced regarding national health shows that these reductions have done no material harm. In the small proportion of people who consistently ate and drank too much there has probably been an actual improvement in health. Improved economic circumstances, the more even distribution of essential foodstuffs brought about by rationing, the introduction of National Flour and the fortification of certain foodstuffs have certainly prevented any further deterioration in the diet of the less fortunate section of the population who could not buy an adequate diet before the war and in at least certain categories (pregnant women, infants and school children) have led to improvement.

War inevitably brings a great impetus to scientific research of all kinds. The success of the Government's wartime food policy can be attributed largely to the sound scientific basis on which it was founded. It is to be hoped sincerely that those wartime measures which have been shown to be of such value to the people's health, e.g. priority rations of milk for infants, school children and pregnant women, school meals and works canteens, and National wheatmeal bread will be continued as part of the permanent peacetime food policy.

CHARLES BARON, M.D.

Pijon, M., and Lozner E. L.: Vitamin C Economy in the Human Subject *Bull. Johns H. phys. Hosp.* 1944, 75, 303.

One subject was placed on a diet without vitamin C until there was a steady linear decline of the white-cell-platelet values of the blood. After twenty-one months on constantly maintained low values, no scorbutic manifestations had appeared and healing of an experimental wound appeared normal. Six subjects saturated with ascorbic acid for from four to six days were then placed on a diet which was normal as to a lack of vitamin C. None of the subjects developed scurvy until after five or six months had elapsed and they seemed normal in all respects until two weeks prior to the onset of the disease.

It seems that the adequate intake of vitamin C should be between the protective minimum (from 18 to 25 mgm. daily) and the amount required to maintain saturation as represented by excretion in the urine (from 80 to 100 mgm. daily). In the absence of clinical evidence the precise intake between the minimal protective dose and the saturation dose is largely a matter of conjecture. If a subject has been initially saturated with ascorbic acid and is then deprived of vitamin C, a period of protection against scurvy exists for as long as five or six months.

WALTER H. NADLER, M.D.

Nielsen, J. M.: A Subacute Generalized Neuromuscular Exhaustion Syndrome *J. Am. M. Ass.* 1944, 136, 501.

Four cases are reported of neuromuscular exhaustion followed by atrophy and fascicular twitching requiring months for recovery. This syndrome believed to be due to neuromuscular exhaustion has not been described in the literature.

Since the cases reported were not studied during the first weeks of the disability, no chemical studies were carried out. During a period of euphoria with oblivion to fatigue the individuals continued to work until the sudden onset of complete neuromuscular exhaustion approaching paralysis. Psychomotor restlessness continued, pains and tenderness were prominent, the muscles became flabby then twitched and atrophied. Paralysis supervened with great loss of body weight. Recovery was delayed for months. In the most severe cases the condition was not entirely overcome. Exacerbations were apt to follow relatively slight exertion. The patients were not neurasthenic and were inclined to ignore their disability.

WALTER H. NADLER, M.D.

Vieta, H. R.: Myasthenia Gravis Treated with Large Doses of Neostigmine Methylsulfate, Intramuscularly and Intravenously, and with Neostigmine Bromide Orally *Am. J. M. Sc.*, 1944, 208, 701.

An American of sixty-eight years, who had previously been a missionary in India with malaria and diarrhoea, presented a severe advanced condition of typical myasthenia gravis, for which he was given eight weeks of intensive treatment. At first he was

given neostigmine methylsulfate parenterally as he was unable to swallow medications but later he received neostigmine bromide orally. The results were reported in support of the author's contention as to the innocuity and nondevelopment of tolerance following heavy and long-continued dosage with this drug.

Three charts portray in detail the hourly (exclusively parenteral) administration of as high as 510 mgm. per twenty-four hours, of neostigmine methylsulfate for the first three weeks, with later total oral dosages of as much as 510 mgm. of neostigmine bromide as the patient improved. Finally the intramuscular injections consisted of 1 or 1.5 mgm. of the methylsulfate preparation and the intravenous administrations (of which there were not more than one per day) consisted of 1.5 mgm. of the methylsulfate in 1,500 cc. of 5 per cent glucose solution (in subsequent patients as much as 3 mgm.) reinforced with 100 mgm. of vitamin C, 10 mgm. of thiamine chloride, 100 mgm. of nicotinamide, and 10 mgm. of riboflavin, the rate of inflow being 70 drops per minute.

Acquired tolerance did not develop and intestinal stimulation was minimal; there were a few cramps, but only 3 to 4 soft bowel movements each day, without diarrhea. Atropine sulfate (1.6 mgm.) was given only 5 times in the eight weeks, on the other days a few drops of tincture of belladonna were substituted. At the end of eight weeks the patient was being maintained on oral neostigmine bromide as had been done for three months before he entered the hospital. He was now able to take as much as 2,400 calories of food daily and was nearly symptom free.

JOHN W. BRIDGMAN, M.D.

Winsor, T., and Dureh, G. E.: Differential Roles of Layers of Human Epigastric Skin on the Diffusion Rate of Water *Arch. Int. M.* 1944, 74, 424.

The diffusion and retention of water by the skin has been a generally recognized function which has not been investigated previously with the detail of the present report.

Diffusion water is defined as water that has passed through the skin to the atmosphere. It is differentiated from the water secreted by the sweat glands. The rate of diffusion of water was determined by means of a specially constructed collecting chamber sealed over the surface of the skin and fitted with an inlet and an outlet tube. The studies were conducted in a controlled air-conditioned room. The average rate of diffusion of water in 13 human subjects was 4.8 mgm. per 5 sq. cm. of surface area in ten minutes. This diffusion water originated from the blood of the skin. The average rate of diffusion of water for cadaver skin was 5.4 mgm. per 5 sq. cm. in ten minutes. With living skin when the temperature is raised past a certain point, secretion water from the sweat glands is also added. In a comfortable environment, the rate of diffusion of water through the skin of patients with atrophic sweat glands was of the same level as that through normal skin. The rate of diffu-

skin through the skin freed from the underlying tissue of fascia, muscle or peritoneum was the same as for skin with its underlying tissues attached. With the epidermis removed the average rate of diffusion was approximately 10 times that of normal skin and indicated that the diffusion restraining layer was located within the epidermis.

After blister formation the rate of diffusion through the denuded surface averaged 41 ± 2 mgm. for 54 sq. cm. in ten minutes. In the latter experiments it was also indicated that the portion of the epidermis superficial to the stratum spinosum contained the inhibiting layer. Tissues or organs without epidermal structures such as the ventricle, the spleen and the placenta, showed no inhibition to the diffusion of fluid. The rate of diffusion of water through the superficial layers of the epidermis contained in the roof of the blister averaged 4.5 mgm. per 54 sq. cm. in ten minutes, almost the same as that through normal intact skin. This finally localized the water withholding function to the keratinized epithelial cells. The inhibiting influence from the colloids of the blister fluid were ruled out. Removal of the corneal layer of the skin by sandpapering resulted in a marked increase in the rate of diffusion of water similar to that obtained after removal of the epidermis by chemical blistering. By other exclusion experiments such as rubbing the skin with gauze it was proved that erythema in itself did not increase the rate of diffusion. Removal of the superficial lipids of the skin with acetone and ether showed that diffusion through defatted skin was essentially similar to that from normal skin. In summary the keratinized portion of the epidermis conserved water loss by inhibition of the diffusion of water. These experiments should be of value in the study of burns.

Burch, G. E. and Winsor T. The Rate of Insensible Perspiration (Diffusion of Water) Locally Through Living and Through Dead Human Skin. *Arch. Int. M.* 1944, 74: 437

Perspiration has been defined as either insensible or sensible. Included in the term of insensible perspiration is diffusion water which must be differentiated from the secretions of the sweat glands. The rate of diffusion of water is influenced by air currents, temperature of the skin, relative humidity, and the electrolyte and protein concentration of tissue fluids. The rate of loss of water through dead skin at the temperature of the normal environment was found to be 5.4 mgm. per 54 sq. cm. per 10 minutes. The accumulation of sweat on the surface of the skin of resting subjects in an environment of 35°C. and 50 per cent relative humidity constantly averaged about 1.5 mgm. When this saturation level was reached it remained constant thereafter. The mean rate of flow was approximately the same in the negro as in the white man which excluded pigment as a factor. The rate of loss of water was not affected by the period of storage of the skin in the refrigerator and the subsequent thawing. In the

Fig. 1. The rate of loss of water through skin of the epigastrum of living subjects resting quietly in bed in a comfortable environment through dead skin of the epigastrum through dead skin of the negro and through dead skin of white subjects. In this figure the mean values are indicated in the center of each column and the extreme values at the top.

latter experiments, the water of diffusion through dead skin excluded any secretion by the sweat glands. It was also found that as the temperature of the dead skin was raised the rate of diffusion of water increased. In a simultaneous study of the loss of water through living intact skin and dead isolated skin there was no significant difference between the two. Other experiments also proved that the water collected from the skin of a subject resting quietly in a comfortable environment was purely that of water of diffusion. The rate of loss of water through the surface of the cover of a large blister showed no significant difference from the rate of loss from the intact normal skin. In 2 subjects with severe atrophy of the sweat glands the rate of water diffusion was the same as that obtained for dead skin in which the sweat glands do not function.

Spiegel, E. A., Oppenheimer M. J., Henny G. C. and Wycis, H. T.: The Experimental Production of Motion Sickness. *War Med. Ch.* 1944, 6: 283

Motion sickness (kinetosis) embraces syndromes such as seasickness, airsickness, car sickness and railway sickness that are induced by similar mechanisms namely repeatedly accelerated and decelerated linear or rotatory motions; these motions are often but not necessarily oscillating.

The testing of a person's susceptibility to motion sickness or changes of this susceptibility under therapeutic measures can be done by means of the Bárány chair. However this chair fulfills the requirements only partially as an angular acceleration is produced only at the beginning and a deceleration at the stopping of the rotation and the spatial relationship of the various parts of the labyrinth to the axis of rotation remains constant during rotation.

Fig. 1. Rotating tilting apparatus for the production of motion sickness. A, Posterior view; B, base; C, side view.

For a quantitative test, changes in position of the head as regularly as possible and in definite directions are necessary. In order to obtain this feature the authors designed the chair and accessories as seen in the accompanying illustration. By the many electrically driven mechanisms, the head is tilted with each turn either in the sagittal or in the frontal plane, so that the angle between the plane of rotation and the plane of the horizontal semicircular canals regularly increases and decreases during each rotation. The same applies to the vertical canals. The effect on the respective canals is the same as if the speed of the motion were regularly changed. In those phases in which certain canals, e.g. the horizontal canals, are most nearly parallel to the horizontal plane the speed of the endolymph movement in these canals is increased; in those phases in which these canals approach the vertical plane, the endolymph movement in these canals is retarded. Thus at regular intervals, the effects of angular acceleration and deceleration on the endolymph flow are produced, and thus the labyrinths (the horizontal as well as the vertical canals) are subjected to mainly the same type of stimulation as in motion sickness.

The rhythmic tilting of the head furthermore produces rhythmic up and down movements of the labyrinths, a type of stimulus occurring not infrequently, e.g. in seasickness (up and down movements of the ship). Thus the labyrinth is subjected to a combination of stimuli.

Symptoms of motion sickness are produced within eight minutes. A comparison of the results with previous experiences of the subjects showed that the weaker method of stimulation (rotation combined with sagittal movements of the head or body) was sufficient to reveal a high degree of susceptibility. The stronger stimulation (rotation combined with frontal head movements preceding or succeeding rotation combined with sagittal head movements) was effective in nearly all moderately susceptible persons and produced symptoms even in some of the persons who were supposedly not susceptible according to previous experiences.

Optic fixation of an object that participates in all movements of the head tends to diminish the inci-

dence of motion sickness as compared with optic fixation of a stationary object situated somewhere in the surroundings.

Typical illusions of spatial orientation were produced. Their appearance was independent of that of the vegetative symptoms of motion sickness, which indicated that two somewhat independent mechanisms are involved.

Symptoms of motion sickness may be elicited not only by stimulation of the maculae but by stimulation of the cristae ampullares.

STEPHEN A. ZIEGLER M.D.

Cameron D. Rodent Ulcer Treated by the Application of Sodium Bicarbonate. *Lancet* Lond 1944 720.

After the local application of sodium bicarbonate in the treatment of rodent ulcer the lesion disappeared in 8 of 16 uncomplicated cases; this was verified histologically.

The sodium bicarbonate was applied on white lint as a simple saturated solution in water, as a water saturated solution with glycerin added to prevent drying, or as water-glycerin lotions or pastes of various strengths. It has also been used as an ointment with 15 or 30 per cent in lanolin, eucerin or soft paraffin. The solutions or pastes were found to be more effective than the ointments.

When solution alone was used there was little or no obvious reaction. When a strong paste was used, the area around the ulcer became red and purulent material came away from the base; this was followed by separation of a slough and exudation of serum. The application of the solution at this stage should result in healing.

Since the salt used is bland, the results obtained are not due to any caustic action. The fact that healing takes place shows that only the malignant tissue is adversely affected by the solution. The action of the sodium bicarbonate may be either direct or indirect. If the action is direct, it may be physical or chemical. Physically the sodium bicarbonate may increase the osmotic pressure of the lymph in which the cancer cells are bathed, and thus damage them. Chemically it may act by heightening the

alkalinity of the lymph. By altering the pH it may inhibit the action of some enzyme, such as the proteolytic one, which constitutes the diffusion factor. If the action is indirect, the salt may by virtue of its solvent properties, remove a local stimulating substance, which has set up carcinogenesis. With removal of the irritant the malignant bias might be gradually reversed.

Whatever the action of sodium bicarbonate it seems to be different from that of radium. It does not impair the effect of radium, and is not prejudiced by the previous use of radium.

The salt may fail in its effect because interposition of fibrous tissue or healthy epithelium prevents its access to the malignant cells or their immediate surroundings.

SAMUEL KAHN M D

Gore, I., and McCarthy A. M : Boeck's Sarcoid. *Surgery* 1944 16 865.

Boeck's sarcoid has come to be regarded as a relatively benign disease of obscure etiology having a predilection for lymphoid tissue but capable of involving any tissue in the body. Despite this potentiality a large proportion of the cases reported are characterized by skin lesions, regional or generalized lymph-node enlargement, a stringy or milky infiltration of the lungs, and cystic changes in the long bones of the hands and feet. In each of these structures the pathological identifying factor is the "hard tubercle" formed of a nodular aggregation of plump polygonal, acidophilic epithelioid cells identical with those found in tuberculosis.

Although lesions have been found in almost every tissue of the body clinical symptoms pointing to involvement of the intestinal tract have not previously been reported.

The authors treated a twenty-six year-old soldier with complaints of burning and sometimes gripping pains in the epigastrium after meals. The symptoms which started June, 1941 were associated with belching and the eructation of bits of food and bitter, hot, slimy material. The patient noticed a loss of weight from 186 pounds in May 1942 to 168 pounds on December 7, 1942. In September 1942 he began to vomit occasionally following meals. Postprandial vomiting became more frequent until the time of hospitalization in December when he could retain very little. The epigastric pain at this time was more or less continuous, both day and night.

Positive findings were limited to moderate emaciation, venereal warts of the prepuce, and moderately enlarged inguinal lymph nodes. Roentgenological examination of the gastrointestinal tract revealed a permanent cone-shaped deformity of the pyloric antrum through which only very shallow peristaltic waves traveled. This rigidity suggested an intramural infiltration of some kind, probably neoplastic in nature. There was no evidence of ulceration or of four hour gastric retention. Stools were negative for occult blood. Three successive positive Wassermann and Kahn serological reactions in January 1943 were reported and syphilis of the stomach was

considered even though the roentgenological findings were not suggestive of this disease. Gastric analyses showed an absence of free hydrochloric acid after histamine the total acidity reaching a maximum of only 20 units. Because the patient failed to respond to antisyphilitic therapy the impression at this time was that he had a gastric neoplasm.

Laparotomy revealed a diffuse doughy thickening of the pyloric stomach. Both the anterior and posterior walls were involved, as well as the greater curvature. The lymph nodes along the omental attachment were markedly enlarged the other viscera appeared normal. Biopsies of the thickened stomach wall and of an enlarged lymph node were taken for frozen section. These revealed the inflammatory nature of the lesion and a provisional diagnosis of gastric tuberculosis or sarcoid disease was made. A gastric resection was performed with the Balfour Polya type of anterior loop anastomosis. Postoperative convalescence was uncomplicated.

The histological diagnosis was (1) Boeck's sarcoid of the stomach and lymph node and (2) subacute ulceration of the pyloric stomach. The preoperative diagnoses considered were peptic ulcer gastric syphilis and gastric neoplasm. Ulceration was undeniably not demonstrated by means of x rays since the ulcer was shallow and its position on the greater curvature did not lend itself to easy demonstration. Furthermore, the presence of achlorhydria, the position of the lesion, and the lack of melena appeared to corroborate the negative roentgenological findings. Peptic ulceration was therefore considered unlikely.

Gastric syphilis was considered a likely possibility because of a rising serological titer, the relative youth of the patient and the position of the lesion in the distal portion of the stomach. However gastric syphilis is considered to be a manifestation of the tertiary phase of the disease. Nonetheless it was considered advisable to institute a therapeutic test of antisyphilitic treatment. There was no response to a short intensive course and after four weeks laparotomy was performed, the presumptive diagnosis being gastric neoplasm.

It is not possible to draw any conclusions as to treatment from one case of surgical sarcoid disease. Each case must be individualized. Although there is a strong tendency toward spontaneous resolution in the primary disease, it is the secondary complication which makes the case "surgical" that must be gauged in treating the patient.

JOSEPH K. NARAT M D

Stuart, B. M : The Sarcoidosis of Boeck. *Am. J. M. Sc.* 1944, 908 717

The condition diagnosed as sarcoidosis of Boeck in young negroes (3 males, 1 female) is reported not because anything could be added to what other writers have offered, but to record the odd coincidence in this small group (3 exemplars) of the urveoparotid syndrome of Heerfort. All 3 patients complained at the time of hospitalization of vague

tuberculous like symptoms such as loss of weight cough of a chronic character and enlarged lymph nodes. Leucopenia and eosinophilia were demonstrable in all, and in each case roentgenographic examination of the chest revealed bilateral hilar enlargement and infiltration in both lungs. In fact, in case 3 tuberculosis was demonstrated later. Biopsy of a lymph node in the girl and in 1 of the boys revealed an almost complete replacement of the normal lymph-node architecture by small and medium-sized circumscribed areas composed chiefly of large epithelioid cells arranged in a concentric manner with a moderate number of lymphocytes near the periphery. Fibers of hyaline connective tissue surrounded each lesion and delimited it from its neighboring lesion. Giant cells were present in an occasional lesion. Caseation necrosis was minimal and present only in a few of the circumscribed areas.

In 1 of the young men the eyes were apparently not involved, while in the young woman and the other male there was unmistakable evidence of the eye involvement characteristic of Heerfordt's syndrome. Slit lamp studies of the girl's eye on the right side revealed numerous grayish, keratic precipitates of various sizes, and inflammatory cells in the aqueous humor. In the boy both eyes were involved, while in the girl only the right eye showed involvement; however, in the latter even macroscopically there was observable a large inflammatory cauliflower cyst of the iris at 7 o'clock near the margin and a smaller cyst of the iris at 5 o'clock nearer the base.

In the girl both lacrimal and both parotid glands were enlarged but not tender. In 1 male the cervical, axillary, epitrochlear and inguinal lymph nodes were moderately enlarged, but neither the lacrimal nor parotid glands were involved. In the other male (the other case of Heerfordt's syndrome) there was a generalized enlargement of the cervical lymph nodes; however, there was only a suggestive enlargement of the right parotid gland.

JOHN W. BREDMAN, M.D.

DUCTLESS GLANDS

Lipton, R. W., and Abel, M. S.: Aspiration Biopsy of the Thyroid in the Evaluation of Thyroid Dysfunction. *Am J Med Sci.*, 1944, 208: 736.

Numerous clinical and laboratory tests for the diagnosis and evaluation of thyroid dysfunction are in use. There is a group of cases, however, in which the laboratory and clinical findings are at variance, hence a definite diagnosis cannot be made. The basal metabolism test, which is the standard procedure for laboratory diagnosis, has certain limitations in its interpretation. Two other valuable laboratory procedures are the determination of the blood-cholesterol levels and the galactose-tolerance test, but these like the basal-metabolism test, are affected by extra-thyroid pathology. Other laboratory and clinical tests have been found to be limited in their scope and interpretation.

The direct method of tissue examination is the final diagnostic criterion. Diagnosis by means of biopsy is the most accurate. When the tissue can be approached easily enough of an excision can be made for ordinary histological section. More inaccessible tissue can be obtained by aspirations with a needle and syringe. The principal difficulty with aspiration biopsies is the very small amount of tissue obtainable which often makes the ordinary histological diagnosis unsatisfactory.

Abel has introduced a method of histological diagnosis of thyroid disease which is based on a microscopic examination of the thyroid acinar cells. Since this method utilizes the dimensions of the cells themselves, and not the general architecture of the gland, it can be used with very small amounts of tissue, and suggests that aspiration biopsies can be used for the direct diagnosis of thyroid disease.

In order to make the aspiration biopsy for thyroid diagnosis as simple and as atraumatic as possible, the authors have developed the following technique:

A No. 18 or a No. 16 gauge 2 inch intravenous needle and an ordinary 30 cc. syringe are used. It is necessary for the needle to be sharp and the syringe to be fairly new so that the barrel and piston do not fit loosely. Tissues obtained are placed in 5 per cent formalin and are treated as regular paraffin sections to insure uniformity of results. A sedative may be given to the patient twenty minutes before the aspiration. The patient should be lying flat with the neck slightly hyperextended. The gland is palpated and a small area in the midline of the neck close to the gland is prepared aseptically and a wheal is raised in the skin with 1 per cent procaine. Some of the solution is injected continuously along the line of the intended puncture down to the gland. A small nick is made through the skin with a bistoury-pointed scalpel (No. 11 B P blade) with the instrument held at right angles to the skin surface. This puncture of the skin facilitates insertion of the needle and prevents its becoming plugged with surface epithelium. The needle with the syringe attached is introduced tilted at about 30 degrees to the sagittal plane. It is advanced slowly through the superficial tissues until the point is felt to enter one or the other of the lateral lobes, whichever seems the more accessible. This technique will avoid the trachea, and the other important structures as shown in Figure 1.

The extreme care with which this aspiration biopsy must be done is apparent from the amount of description of the procedure given by the authors.

Microscopic examination of the aspiration specimens shows only small particles of the gland in a large amount of blood. Closer examination under the oil-immersion lens reveals that these gland particles consist entirely of acinar cells, arranged in acini and portions of acini from which the colloid material is entirely gone. Apparently the force of the aspiration is chiefly exercised on the cells and the colloid is squeezed out and left behind. If only single cells are left, the acinar cells appear to be intact and undistorted in their acini and remnants of acini.

Fig. 1 Transverse section of neck at level of sixth cervical vertebra illustrating an aspiration needle in place

Abel used the criterion that an average cell height of over 5.8 units indicated toxicity in nodular goiters, a height of over 5 units indicated toxicity in diffuse goiters, and a height of less than 5 units indicated a normal gland. Each of his units equalled 1.4 microns which gives us the following standards to go by:

1. An average cell height of over 8.1 microns indicates toxicity in nodular goiters
2. An average cell height of over 7 microns indicates toxicity in diffuse goiters.
3. An average cell height under 7 microns indicates a normal gland. These standards for cell heights were used as a criterion for diagnosis. The measurement of the thyroid acinar cells as described by Abel was performed with a micrometer scale fitted into the eyepiece of the microscope, which was used on an oil immersed objective. In all cases the diameter of a cell was measured at a point crossing the nucleus and on a line along the radius of an acinus. The cells were measured in blocks of 100 from 100 separate acini chosen at random where the scale happened to fall as the slide was systematically moved across the stage. The only provisos were that the acini be open and that the cell boundaries be distinguishable.

By means of this procedure aspiration specimens from 20 thyroid glands were examined microscopically and 100 acinar cells measured from each. Later sections from surgical specimens were studied from each of 17 glands and in each instance 100 acinar cells were measured and the results compared with those from the aspirations and with clinical data. The measurements obtained from the aspiration specimens agreed very closely with those from the surgical specimens. It was found that a diagnosis of toxicity could be made on 16 of the first 17 aspiration specimens by the measurements alone. Aspirations done on 3 normal cases likewise confirmed the accuracy of the test and helped to confirm the standards for cell heights used as the criterion of

diagnosis. The average cell heights in these instances were all under 7 microns as would be expected in normal cases. In the cases described the measurement of acinar cell heights of thyroid aspiration specimens were of the magnitude expected and confirmed the diagnosis of toxicity in a majority of cases.

The present direct method may prove to be a valuable adjunct in the diagnosis of thyrotoxicosis

MATHIAS J. SEEVER, M.D.

Pomberton J. deJ. and Black, B. M. Goiter in *Children Surgery* 1944, 16: 756

From 1908 through 1943 189 children fourteen years of age or less with exophthalmic goiter were seen at the Mayo Clinic. In most cases thyroidectomy was carried out at the clinic, but 14 patients were treated medically with results that were considered good in 10 fair in 3 and poor in 1. Thyroidectomy was performed in 164 patients 8 dying while in the hospital. Fifty-five patients were operated on during the period before medication with iodine was instituted with 5 deaths. One hundred and nine children were operated on after having been prepared for operation with iodine with 3 deaths, a hospital mortality rate of 2.8 per cent. Since the preoperative use of iodine the late results after thyroidectomy have been satisfactory. Of the group of 102 patients who survived operation done since the use of iodine was instituted and on whom follow up data are available 1 died from the results of hyperthyroidism, 7 have had recurrent exophthalmic goiter and 23 have developed low basal metabolic rates or myxedema.

Fifty-two children, fourteen years of age or less with adenomatous goiter were seen at the clinic from 1917 through 1943. In no case was the basal metabolic rate elevated. Adenomatous goiter with hyperthyroidism has never been encountered in children at the clinic. Fourteen patients were operated on and the remainder were treated medically. The adenomas

seemed to differ in no way from those found in the goiters of adults.

From 1908 through 1943 a total of 53 children with nodular goiters were operated on. In 31 cases the nodularity was caused by adenomas in 3 cases by thyroiditis, and in 18 cases by malignancy. In 5 cases of carcinoma, enlarged cervical lymph nodes overshadowed the enlargement of the thyroid, but in the other 13 cases the nodularity was largely confined to the thyroid gland. Thus, 1 in 3 nodular goiters in the children operated upon were malignant.

In 17 of the 18 children with carcinoma of the thyroid gland, the tissue diagnosis was adenocarcinoma of either grade 1 or grade 2 malignancy. Thirteen of the adenocarcinomas were of the papillary type and 2 were noted to have developed in fetal adenomas. In 1 case the adenocarcinoma was of grade 4 malignancy. The lesion was judged operable in 10 cases and inoperable in 8. In every case in which metastasis had developed, 11 in all, the cervical lymph nodes were involved in 4 cases pulmonary metastasis developed and in 1 case metastatic tissue was found in the calvarium and in the spinal column. Whether or not the lesion was resected irradiation therapy was carried out in all but 1 case in which death occurred following biopsy.

Beardwood, J. T. Jr., and Levinson D. C.: Thiouracil in the Medical Management of Hyperthyroidism. *P. amsyloids M J* 944, 43 12.

The authors have used thiouracil in 30 cases of thyrotoxicosis, the duration of treatment varying from four to nine months. The series includes diffuse hyperplastic glands, toxic adenomas, and adenomatous colloid goiters. In 18 of the 30 patients the basal metabolic rate returned to normal, accompanied by clinical remission, weight gain, and elevation of the serum cholesterol. Therapy in 1 patient was discontinued because a leucopenia developed after the basal metabolic rate had fallen from plus 73 to plus 37. The time necessary for the basal metabolic rate to return to normal varied from one to fourteen weeks. Three patients requiring more than seven weeks for the return of a normal metabolism had been on iodine therapy prior to the thiouracil treatment. This confirms the findings of others that previous iodine therapy tends to delay the response to thiouracil.

In 4 of 5 patients whose treatment with thiouracil was stopped relapse followed but this was promptly controlled by the resumption of therapy. It appears advisable to give a maintenance dose of thiouracil over a long period, in an attempt to tide the patient over until the disease has exhausted itself rather than to employ intermittent therapy.

All patients were treated initially with gm. of thiouracil daily in 5 divided doses. The dosage was reduced as the basal metabolic rate dropped when this became normal a maintenance dose of from 0.1 to 0.4 gm. daily was given.

The only serious complication was leucopenia, which developed in 3 patients. Other transient reac-

tions which disappeared during continuance of the treatment were periorbital edema, leg edema, and hoarseness. A lower initial dosage should tend to diminish the frequency of these reactions. Metabolic studies of the serum cholesterol, urinary creatinine excretion and galactose thyroid function indicated the action of the drug to be physiological. There were 3 thyrocardiac patients in the series, all of whom were in decompensation. With thiouracil, the basal metabolic rate returned to normal, the heart action became less forceful, and the auricular fibrillation reverted to normal sinus rhythm. Thiouracil will probably find its greatest value in the management of thyrocardiac patients, who are frequently inoperable.

JOHN L. LINCOLN, M.D.

Rosa, E., and McConnell, J.: Thiouracil in the Treatment of Thyrotoxicosis. Clinical Experience with 37 Cases. *Am. J. M. Sc.*, 944, 308, 561.

In 1943 Mackenzie and Mackenzie, and Astwood and his associates first reported in detail the striking effects of thiourea and related compounds upon the structure and function of the thyroid gland in lower animals. Thiourea and its related compound, 2-thiouracil, inhibit the synthesis of the thyroid hormone, probably by affecting an enzyme system in the gland which normally aids in the conversion of iodine into the completed hormone.

The authors describe their clinical experiences with 37 thyrotoxic patients treated with 2-thiouracil. Thirty patients (81 per cent) showed a favorable response, 4 (10.9 per cent) showed a partial response, and 3 (5.4 per cent) showed no response to treatment. Three of the 6 patients showing unsatisfactory response presented associated conditions which may have influenced their reactions.

In 4 patients thiouracil was used during their preparation for thyroidectomy. One of these died twenty hours after operation, but the thiouracil was not regarded as a factor in the death. Autopsy in this case showed no lesions which could be associated with the use of thiouracil.

The control of thyrotoxicosis with thiouracil in a thirteen year-old girl with diabetes mellitus was not followed by an increase in carbohydrate tolerance or a decrease in insulin requirement.

The histological appearance of the thyroid gland in patients prepared for thyroidectomy with thiouracil showed the hyperplasia and other changes previously reported by others.

Eight patients have shown remission of their toxic symptoms for periods varying from three weeks to seven months following the complete withdrawal of thiouracil on minimal doses (from 0.1 to 0.5 gm. daily). 3 patients have responded likewise. Thirteen patients relapsed when the drug was either reduced in dosage or withdrawn. All of these patients, however, again responded to readministration of the thiouracil.

Measurements of the cardiac output by means of the ballistocardiogram in 9 patients showed a general

tendency toward a reduction in output under thionuracil therapy which was roughly parallel to the decline in the basal metabolism

No evidence of the development of refractoriness to thionuracil was observed. Untoward reactions attributable to the drug occurred in 8 patients. The most important of these was neutropenia with pharyngitis and fever noted in 2 cases. Reduction in the size of the thyroid gland was noted in 8 patients after prolonged treatment. Exophthalmos tended either to remain stationary or to increase slightly.

The authors raised a number of important questions regarding the effect and clinical usefulness of thionuracil. Among these are

1. What late toxic effects may follow its prolonged use? Is it possible for example that depression or exhaustion of the bone marrow might follow the prolonged ingestion of the drug in some cases?

2. What undesirable dislocations of endocrine relationship might be induced by prolonged inhibition of the thyroid-pituitary balance? Is there thus a possibility that hyperfunction of the pituitary might eventually be produced or that pituitary exhaustion might ensue? Is it possible that the maintenance of a chronically hyperplastic state of the thyroid might be followed by fibrosis atrophy or neoplastic change?

3. What is the effect of thionuracil upon the structure and function of the normal human thyroid gland? Much additional work appears desirable to explain the discrepancy between the consistent effects of thionuracil in normal lower animals and its apparent lack of effect of the normal human being.

4. What types of thyrotoxicosis will respond best to thionuracil, and how long must such cases remain under treatment before a permanent cure is effected?

5. Could the therapeutic response in thyrotoxicosis be enhanced by the coincidental use of anti-pituitary agents such as irradiation, estrogens or nadrogens?

The ability of most patients to remain ambulatory or even to continue at work, while under treatment for long periods of time constitutes an important advantage. Bed rest at the initiation of treatment shortened the time of response.

The authors come to the tentative conclusion that the drug effectively controls most of the phenomena of thyrotoxicosis in the large majority of patients and that its use at present is justified in the protracted treatment of mild or moderately severe cases and in the preoperative preparation of selected patients for thyroidectomy. It may also prove of considerable value in patients regarded as unacceptable surgical risks.

JOSEPH K. NARAT M.D.

Coburn, D. E.: Severe Osteitis Fibrosa Cystica with Parathyroid Tumor. Report of a Case of Fifteen Years Duration. *Am. J. Surg.*, 1944, 66: 352.

A severe case of generalized osteitis fibrosa cystica due to parathyroid adenoma is reported the tumor being located in the superior mediastinum. The case

was remarkable in that the symptoms dated back over a period of nearly sixteen years during which time the patient suffered 4 fractures and 1 operation for kidney stones. The skeletal involvement was extensive and included both patellae a site which has not been previously reported. Postoperative convalescence was marked by a fracture of the right femur which suggested that in the postoperative care of these patients precautionary splinting might be applied to the bones of the extremities which are extensively involved until some degree of recalcification has occurred.

SAMUEL KAHN M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Fleming, A.: Micromethods of Estimating Penicillin in Blood Serum and Other Body Fluids. *Lancet* Lond., 1944, 247: 630.

There is no chemical test for penicillin in blood, but the concentration of this substance in blood serum can readily be estimated by titration of its bacteriostatic power on a suitable test organism. This titration can be done in test tubes with volumes of 0.5 c.c.m. or 1 c.c.m. However since blood specimens have to be taken at frequent intervals and since large amounts of blood are required for the tests, this procedure was considered unjustifiable.

Microtitration tests have previously been described but they have now been modified. The detailed technique for performing microtitrations of penicillin in the body fluids of patients who are being treated by the drug is given. In this technique, slide cells or capillary tubes are used as cultural vessels the hemolytic streptococcus is the test organism and blood is the indicator.

SAMUEL KAHN M.D.

Troll, M. M.: Aberrant Pancreatic and Gastric Tissue in the Intestinal Tract. *Arch. Path. Chic.* 1944, 38: 375.

The presence of ectopic tissue in 8 cases is reported. In 3 cases the tissue was pancreatic, occurring in Meckel's diverticulum in 2 instances and in the ileum in 1 instance. In 6 of the cases gastric mucosa was observed in Meckel's diverticulum, and in 1 of these cases the diverticulum contained both pancreatic tissue and gastric mucosa. The 3 instances of aberrant pancreas in Meckel's diverticulum are the twenty fourth and twenty fifth cases to be reported while the case of pancreatic tissue in the ileum makes the twenty first in the literature.

The theory that the tissue was transplanted from the original site during embryonic development is believed to be the most acceptable of the 3 theories on the pathogenesis of the aberrant pancreas and gastric mucosa which were reviewed.

WALTER H. NADLER, M.D.

Schrek, R.: The Racial Distribution of Cancer II. Tumors of the Kidney Bladder and Male Genital Organs. *Ann. Surg.*, 1944, 120: 809.

The incidence of cancer of the genitourinary tract in the white and colored races was studied indirectly

by the method of determining the percentage of colored patients in the tumor and in the control groups.

According to this study cancer of the penis and scrotum, and possibly cancer of the prostate, occurred relatively more frequently in colored than in white men. Colored men below the age of fifty had a relatively low incidence of cancer of the testis but negroes above the age of fifty had the same incidence of this tumor as the white men. Colored men, but not colored women, had a relatively low incidence of cancer of the bladder. Tumors of the kidney occurred equally frequently in white and colored individuals.

EXPERIMENTAL SURGERY

Large, A. and Heinbecker P: The Effect of Cooling on Wound Healing. *Ann. Surg.* 944, 120 7 7

Experiments on dogs were carried out by the authors with a view to studying the effects of prolonged refrigeration on wound healing. The nature of the healing process in clean incised wounds of the skin and subcutaneous tissues of the forelimb after cooling to 6°C. for a period of from twenty-four to seventy-two hours was determined. Similar incisions on the opposite limb were used as controls. The healing process was studied by measurements of the tensile strength and by microscopic examination of the wounds at varying intervals. The results showed that during the cooling period there was no reaction on the part of the tissues to the injury inflicted by the incision, but subsequently there was a definite delay in the healing of the wounds, the degree of delay varying with the duration of the cooling period. In wounds treated by delayed suture after cooling for from twenty-four to forty-eight hours the incidence of infection is much greater than in control incisions maintained at normal temperatures.

The results of the authors' experiments indicate that certain harmful effects result from prolonged refrigeration of living tissue such as is advocated by some for amputation of gangrenous-infected extremities. It may be held that as the clinical cooling period is often much shorter than the cooling period in these experiments the results are not comparable. Since it has been shown that the harmful effects are proportional to the duration of the cooling period, it may be assumed that some degree of harm must result whenever living tissues are cooled to low temperatures. Therefore it is believed by the authors that refrigeration anesthesia is not ideal for amputations. If the aim is to diminish absorption from a gangrenous region by local cooling this can be accomplished by refrigerating the limb below the desired amputation level in order that the anesthesia so induced will permit the application of a tight tourniquet. After restorative measures have been effective amputation can be carried out under ordinary anesthesia above the level of cooling without harmful sequelae.

Suggestions have recently been advanced that wounds of the extremities which have been incurred on the battle field should be refrigerated during transportation and until proper emergency surgical treatment can be instituted, an interval of many hours or even days. The authors' experiments dealing with the effect of prolonged cooling on wounds treated by delayed or secondary suture fairly closely approximate such war conditions, and because of the increased incidence of wound infection after the cooling period in these experiments, it is recommended that wounds sustained on the battle field should not be treated by refrigeration unless there is no hope of saving the part.

JOSEPH K. NARAT, M.D.

Brunessu, J., and Heinbecker P: The Effects of Cooling on Experimentally Infected Tissues. *Ann. Surg.* 944, 20 7 6.

The effects of reduced temperatures on tissue survival under anoxia and on tissue resistance to infection have been the subject of several recent investigations. The authors report their results of an investigation to determine the effects of reduced temperatures on both the local tissue response and the organisms responsible for it and to determine the eventual course of a local infection as altered by a temporary period of cooling. A concentrated suspension of the streptococcus hemolyticus in broth was used to produce a localized infection in dogs. Cooling was effected by immersing the limb to a level well above the elbow in a constant temperature bath provided by a commercial cooler. The experiments were carried out for periods ranging from twenty-four to ninety-six hours.

The authors concluded from their experiments that as long as cooling to 6°C. is maintained, the subcutaneous tissues of the dog fail to show the inflammatory response usually initiated by the inoculation of the streptococcus hemolyticus. The number of organisms present in the tissues remains remarkably constant and closely approximates the number injected.

The development of extensive subcutaneous edema during cooling and after removal of the cold, and the development of a more marked inflammatory reaction, with a decrease in the growth restricting power of the tissues to bacterial organisms, suggest the possibility of harmful effects from prolonged refrigeration. The effects of cooling are manifest in the deeper as well as in the superficial tissues of the limb of a dog with an intact blood supply.

From these experimental data, it seems evident that the clinical application of cold (6°C.) to infected tissue will have no therapeutic value in itself. Under certain circumstances it may not be harmful to cool an infected limb for a brief period in order to maintain the relative status quo observed in these experiments in regard to bacterial activity and to tissue response. However cooling for longer periods of time (from twenty-four to ninety-six hours) in the authors' experiments resulted in definite changes in tissue hydration, marked vasodilatation, and a de-

crease in the growth-restricting action of the tissues toward bacterial organisms. Moreover these changes became more marked as the period of refrigeration was prolonged. While the exact clinical limitations of the procedure remain to be determined the findings so far would contraindicate the cooling to levels around 6 C. of infected limbs which one aims to save by conservative measures, except for brief periods of time.

JOSEPH E. NARAT M.D.

Ham, A. W.: Experimental Study of the Histopathology of Burns, with Particular Reference to Sites of Fluid Loss in Burns of Different Depth. *Ann Surg*, 1944, 120 689.

The pathology of burns was studied in relation to the blood supply of the skin, because of the importance of the problem of local fluid loss from blood vessels in burns. The pig was selected as the experimental animal since its skin more closely resembles human skin than does the skin of other laboratory animals. Burns of the three degrees were produced in different animals by controlled methods of contact with heat. Grossly the burns produced as a result of contact of shorter duration were characterized by redness of the skin while those due to longer exposure appeared white. The depth of burning is indicated by the resistance of the hairs to being pulled out in deeper burns, fluid that escapes from the capillaries loosens the attachment of the hairs.

A histological study of first-degree burns showed dilatation and congestion of the superficial plexuses of capillaries and venules. (These vessels are the ones concerned in the dissemination of heat.) More severe first-degree burns cause an escape of fluid from these vessels, which may lift the epidermis from the dermis to form small blisters. In these studies all blisters were situated between the epidermis and the dermis.

In mild second-degree burns many of the superficial vessels continue to function and leak fluid. In severe second-degree or white burns the whole superficial group of vessels is sealed off by heat. Although the underlying dermis contains few capillaries much fluid is lost in this type of burn from the intense congestion and dilatation of the capillary beds about the deep secreting portions of the sweat glands and the deepest parts of the hair follicles. It is this escape of fluid that loosens the hair attachments. Fluid lost from this part of the capillary bed readily finds its way to the subcutaneous tissue and it appears that the subcutaneous accumulation of fluid in this type of burn has its origin in the skin.

In very severe second-degree and in third-degree burns, fluid loss actually occurs from the capillaries of the subcutaneous tissue since marked congestion of these vessels with perivascular accumulation of fluid is apparent histologically.

Experiments in which trypan blue was injected intravenously confirmed the histological findings. This dye does not ordinarily escape from the capillary bed fast enough to produce intense diffuse

staining of the tissues. However when plasma escapes into the tissues following burns the presence of trypan blue in the plasma stains the areas of accumulation a deep blue.

These studies also indicated that there are two capillary beds in the skin and one in the subcutaneous tissues which are the chief sites of fluid loss in burns of different intensities. JOHN L. LINQUIST M.D.

Ham, A. W. Experimental Study of the Tannic Acid Treatment of Burns, with Particular Reference to Its Effect on Local Fluid Loss and Healing. *Ann Surg* 1944, 120 698.

An experimental study was made to determine the effectiveness of tannic acid treatment of burns in limiting local fluid loss and its efficiency in this respect with burns of varying degree. Young hogs were used as experimental animals because of the similarities of hog and human skin. Burns of varying degree and the subsequent tanning were produced by controlled methods following which sections of the skin were prepared for histological examination. Epidermis was found to be a barrier to the penetration of the tanning agent so that it was necessary to remove the epidermis with a sharp scalpel before application of the tannic acid.

When tannic acid is applied in successive coats to a burned surface denuded of epidermis it penetrates remarkably evenly into the dermis presumably by combining with collagen in much the same fashion that it does in the manufacture of leather. The depth of penetration depends upon the length of time that the surface is kept wet with tannic acid. Many hours of exposure resulted in a penetration of a quarter up to a third of the thickness of the dermis. Combining with the collagen is not the only effect of tannic acid on the dermis. It also kills viable elements in the dermis for a considerable distance below the layer that is frankly tanned and results in a gathering of leucocytes along a line beneath this dead layer. Both layers separate off in the eschar at the line of leucocytic concentration.

Since it has been shown that the chief fluid loss in first-degree and in mild second-degree burns occurs from the superficial plexuses of capillaries tanning of the surface would tend to prevent this loss. In deeper burns however it has been shown that the fluid loss occurs from the capillaries about the deeper portions of the sweat glands and hair follicles at a level that is not reached by the tannic acid. Tanning could not be expected to diminish fluid loss from these deeper burns in the same direct way that it does so in more superficial burns. Experiments with trypan blue given intravenously showed that keeping the tanned or even untanned surface of the burned area dry was efficacious in preventing trypan blue leakage from a first-degree or mild second degree burn. In deeper burns tanning was found to exert little or no effect on the amount of trypan blue that escaped at the burn site.

Tanning necessarily slows the healing of a very superficial burn in which the complete thickness of
